LIST OF CONTRIBUTORS TO VOL. XXXIII.

Abbe, Dr. Robert, New York.
Ambrook, Dr. Charles, Boulder, Col.
Anderson, Dr. B. P., Colorado Springs, Col.
Atkins, Dr. E. C., Milford, Mass.
Atkins, Dr. Francis H., Las Vegas, N. M.
Ayers, Dr. Edward A., New York.

Barber, Dr. C. F., Brooklyn, N. Y.
Barker, Dr. Fordyce, New York.
Baruch, Dr. Simon, New York.
Belfield, Dr. William T., Chicago, Ill.
Bernays, Dr. A. C., St. Louis, Mo.
Bodenhamer, Dr. William, New York.
Borck, Dr. Edward, St. Louis, Mo.
Boyd, Dr. J. M., Knoxville, Tenn.
Bressler, Dr. Frank C., Baltimore, Md.
Brown, Dr. Elizabeth Stow, New York.
Brown, Dr. John Young, Henderson, Ky.
Browne, Mr. Lennox, London, Eng.
Buckmaster, Dr. A. H., Brooklyn, N. Y.
Bull, Dr. William T., New York.
Burchard, Dr. T. H., New York.
Burnett, Dr. Swan M., Washington, D. C.
Burrows, Dr., Lindsay, Ont.

Caillé, Dr. Augustus, New York.
Cammann, Dr. D. M., New York.
Carleton, Dr. C. G., Lawrence, Mass.
Carmon, Dr. F. W., New York.
Carpenter, Dr. A. B., Cleveland, O.
Castle, Dr. Frederick A., New York.
Chapman, Dr. E. A., Belleville, N. J.
Chappell, Dr. W. Franklin, New York.
Cheesman, Dr. Hobart, New York.
Cheesman, Dr. William S., Auburn, N. Y.
Chisolm, Dr. Julian J., Baltimore, Md.
Church, Dr. Charles A., Bloomingdale, N. Y.
Clarke, Dr. John M., Burlington, Vt.
Cleveland, Dr. E. S., Burlington, Kan.
Coe, Dr. Henry C., New York.
Comstock, Dr. T. Griswold, St. Louis, Mo.
Conkey, Dr. Caroline R., Watertown, N. Y.
Corning, Dr. J. Leonard, New York.
Crothers, Dr. T. D., Hartford, Conn.
Curtis, Dr. B. Farquhar, New York.

Dabney, Dr. S. G., Louisville, Ky.
Da Costa, Dr. J. M., Philadelphia, Pa.
Dana, Dr. C. L., New York.
Dawley, Dr. L. B., Binghamton, N. Y.
Deane, Dr. W. H., Blandford, Mass.
Delafield, Dr. Francis, New York.
Deming, Dr. W. C., New York.
Derby, Dr. Richard H., New York.
Dibble, Dr. Le Roy, Kansas City, Mo.
Drzewiecki, Dr. Joseph, Warsaw, Russia.

Edwards, Dr. F. W., Wilmot Flat, N. H.
Edwards, Dr. R. T., Vicksburg, Miss.
Elliott, Dr. George R., New York.
Epps, Mr. Washington, London, Eng.

Finlay, Dr. Charles, Havana, Cuba.
Fisher, Dr. F. J. T., Elmhurst, Ill.
Fliesburg, Dr. Oscar A., Hudson, Wis.
Foster, Dr. J. W., Kansas City, Mo.
Fothergill, Dr. J. Milner, London, Eng.
Fox, Dr. George Henry, New York.
Fridenberg, Dr. A. H., New York.
Fuchs, Dr. A. F., Fredonia, Wis.

Gardinier, Dr. Herman C., Troy, N. Y.
Gardner, Dr. W. H., Fort McHenry, Md.
German, Dr. William H., Morgan Park, Ill.
Gillette, Dr. Arthur A., Westernville, N. Y.
Gillette, Dr. H. F., Cuba, N. Y.
Girdner, Dr. Harvey, New York.
Gleitsmann, Dr. J. W., New York.
Goldenberg, Dr. Herman, New York.
Gottheil, Dr. W. S., New York.
Graddy, Dr. L. B., Omaha, Neb.
Griffin, Dr. E. Harrison, New York.

Hall, Dr. C. H. H., Yokohama, Japan.
Harlan, Dr. Herbert, Baltimore, Md.
Harrison, Mr. Reginald, Liverpool, Eng.
Hartwig, Dr. Marcell, Buffalo, N. Y.
Herrick, Dr. O. E., Grand Rapids, Mich.
Hill, Dr. Horace G., Philadelphia, Pa.
Hogeboom, Dr. Charles L., Jamaica, N. Y.
Holmboe, Dr. A., Chicago, Ill.
Holt, Dr. L. Emmett, New York.
Homans, Dr. John, Boston, Mass.
Hopkins, Dr. George Edward, New York.
Hunter, Dr. James B., New York.

Jacobs, Dr. C. C., Frostburg, Md.
James, Dr. M. B., New York.
Jones, Dr. E. J., Oak Hill, O.
Judson, Dr. A. B., New York.

Original Articles.

THE NEUROTIC, WITH INDIGESTION AND LITHIASIS.

BY J. MILNER FOTHERGILL, M.D.,

PHYSICIAN TO THE CITY OF LONDON HOSPITAL FOR DISEASES OF THE CHEST; AND HON. M.D. OF RUSH MEDICAL COLLEGE, ILL.; FOREIGN ASSOCIATE FELLOW OF THE COLLEGE OF PHYSICIANS OF PHILADELPHIA.

THE subject of indigestion, in combination with the uric-acid formation, is one which must possess a high interest for American physicians, for the excellent reason that they must so constantly encounter it.

It is a malady *par excellence* of town-dwellers. It belongs to the individual of thin flank. The robust, bulky country squire, with his hands and feet deformed and unsightly from gout, has his counterpart in the lean, spare, dyspeptic town-dweller. The type represented by the massive country squire is rare in the United States, where even dwellers in the country are lean, as a rule. Taking old England, which member of the family is it who makes for the town? The neurotic member, who kicks against the monotonous life of the rustic, who chafes under that dependence upon the weather which agriculture entails. Just as the old Puritans of New England were those men who would not indorse the tyranny of Charles I., and who emigrated to face the wilderness and the red man rather than stay longer under his rule. No wonder the descendants of these men are more distinctly neurotic than their English cousins, —the children of those who were content to bide at home. If the neurotic member of the family is the one *par excellence* who chooses a town-life, he is, to my mind, not the one who endures it best; *i.e.*, himself, or his descendants. If he personally gets along well enough, his children will manifest the influence of town-life upon their physique. They are delicate in childhood; they grow up dyspeptics. Their children, despite all care, succumb to the maladies of childhood. Each generation is more markedly neurotic till it comes to that bundle of nerves with shrunken viscera—the girl whose uterus remains infantile, and who is the last of her family. It is a terrible story—is it a true story? That is the question. I am seriously afraid it is a true story.

Not that the race is growing puny. The modern Scandinavians cannot get their hands into the hilts of the swords of the old Vikings. At the Eglinton tournament nearly every man had to have his ancestor's armor "let out"—(probably this was not the term used by the armorer, but it is the modern equivalent). The measurements of ready-made clothes out in the Western States are enlarged to meet the wants of the stalwart youngsters of to-day. On the other hand, the standard of height for soldiers is falling. There are so many little men about now. Town people are undersized. The slight, active-brained neurotic spurns the country and seeks a congenial life in a town.

This neurotic townsman is usually an energetic, hard-working fellow. Certainly he is such in the United States. An affectionate husband he is, for he is distinctly erotic. He is a kind father, very fond of his bright, slight, quick-witted daughters. He likes to see his sons throw themselves heart and soul into their business. What they have to do they do with a will. This is all very well; but behind that neurotic family group a shadowy spectre can be detected by a quick eye. Nature knows nothing of extenuating circumstances. If a family leads an unnatural life they must pay the penalty. "The expansive energy of steam will slay not only the wicked engineer who has neglected his boiler, but also the innocent children playing on the deck overhead.

'Streams will not curb their pride
The just man not to entomb;
Nor lightnings go aside
To leave his virtues room.'

But the flood and the earthquake, like the wickedness of men, in so far as the arrangements of society are not yet adequate for curbing it, must be accepted with resignation as part and parcel of the events which the constitution of our universe necessitates" (Fiske's Cosmic Philosophy). It would seem that a man cannot get the inside track of the Almighty. The Creater has laid down certain laws which the created must obey, or accept the consequences. If a man forsakes the country and becomes a dweller in towns, the first step toward the extinction of his race is taken. Without fresh infusions of new blood from the country his progeny degenerates to extinction in the fourth or fifth generation. Lugol and Boudin say the third generation ends the family in Paris. Hayle Walsh and James Cantlie have found a pure bred Cockney of the fourth generation a rarity. Personally I only know one, a bright little fellow. Cantlie defied the Guildhall authorities to find a pure Cockney of the fifth generation.

The effect of town-life is to degenerate the physique; and neurotic persons are those who feel its effects the soonest and the most severely. At least this is the result of my investigations.

How stands it with the neurotic town-dwelling American when he presents himself in my consulting-room? He is a spare, worn-looking man, complaining of indigestion, acidity, and flatulence. Less commonly he has some skin eruption or other, occasionally he has asthma. He has cold hands and feet. Sometimes he tells that he has observed that he passes more water than he used to do. This evidence of shrinking kidney is accompanied by a large left ventricle, a loud aortic second sound, and a hardening artery—the phenomena of the vaso-renal change (those readers who feel interested in this subject will find it dealt with at length in "Vaso-renal Change *versus* Bright's Disease"). His nails are reedy, and there is a vascular plexus in the conjunctival aspect of the lower eyelids. Commonly the gum is retracted, and the teeth worn down. When asked if there are times when little things put him out, or perturb him out of proportion to their real importance, he replies in the affirmative. Are there sediments in his urine? Yes, pretty constantly. Such is the outline of the dyspeptic of the uric-acid formation, who finds the sipping of hot water to ease the pain in the stomach to which he is subject.

In some, in addition to these phenomena, there are very disagreeable sensations. Those around him say he is "nervous." If they felt what he feels, perhaps they would be "nervous" too. He experiences feelings which throw physical suffering into the background. Last spring my liver was out of order from overwork and east winds, and I then learned enough to comprehend his tale. The whole troop and array of distemperatures vanished (like a horde of evil spirits at the sign of the cross) as soon as an attack of gout fastened on the right foot. Articular gout is not pleasant, but there are worse things than the gout. These unpleasant feelings, to my mind, are linked with the products of later digestion. From three to four hours after breakfast was their favorite time. They would flee after a loose motion of very offensive character, with ill-smelling flatus, or would gradually pass away on getting into the air (probably the offending matters were thus oxidized away). And this personal experience chimes in with the experiences of others. The time of their oncome links them with later digestion. Skatol and indol! Their stench is not less offensive to the nostril than are they to the brain when circulating in the blood. The effect of a mercurial pill and a seidlitz rivets the bond of their association with the liver, which cannot keep them within the portal circulation, but permits of their escape into the general circulation to exercise their toxic influence upon the brain, the organ of mind.

The overworked man is too commonly an individual of sad experiences, and many a man has committed suicide as the only road of escape from his feelings. Lord Byron found Epsom salts the best means of raising his spirits when depressed, and to clear out the alimentary canal is good practice in these cases.

So much for the individual himself. How about his progeny? "What is acquired by the father is inherited by the child." So wrote George Combe. "The fathers have eaten sour grapes, and the children's teeth are set on edge," says a higher authority. The son is the father accentuated, and, as an affluent dyspeptic, at a comparatively early age makes the round of the watering-places of his own country and of Europe. In addition to his father's experience of morbid phenomena he is liable to attacks of very sharp pain in the transverse colon, or the stomach, especially if he has acquired any malarial taint.

But his daughters—the migrainous daughters of hard-working fathers—what sort of womenkind are they? *Petite*, active beings, often birdlike in their walk and movements; quick as lightning; acute, sensitive, highly strung, high-minded and quick-tempered; energetic and industrious; neat in their attire; intolerant of dirt—the sight of a cobweb is agony to them; every sense is highly strung, and, when suffering with migraine, on the stretch, till it is scarcely exaggeration to say that when lying in their bedroom they can hear the cat walking across the kitchen floor. Their complaint is of migraine, "face-ache" or "neuralgia" they call it. A one-sided headache around the eye, with pain in the eye itself, accompanied by sparks or stars, commonly ending in vomiting. They complain of palpitation, and also of an opposite condition of heart-failure, which differs from syncope in that there is no loss of consciousness. The condition is one of intense suffering. They have choking sensations at times, as if they could not get their breath. They complain of indigestion, with acidity and flatulence, while the bowels usually are constipated. They pass water in considerable quantity, especially when excited, and still more decidedly during the attack of migraine. Sometimes they pass water in less quantity, but dense, and highly charged with lithates. They constantly complain of dysmenorrhœa, usually with a scanty loss, but sometimes menorrhagia. Their internal reproductive organs are imperfectly developed, remaining more or less infantile, while the ovaries are tender. Some are quite sexless, others feebly erotic. Some are incapable of impregnation, while others can become pregnant but abort. Some can bear a feeble, delicate child or two; but, speaking broadly, they are not a fertile folk. Commonly, they have rheumatism somewhere, usually in their shoulders, because they have a habit of putting their arms out from under the bedclothes, and throwing them over their heads. These are the people who cannot swallow a pill.

They are charming patients, always attached to their physicians; never out of some doctor's hands long together. Yet they do not get much good, and rarely when they do is it lasting. It is difficult to diet them; for, though they can take good care of any one else, they seem incapable of taking sufficient care of themselves. Experience teaches them comparatively little. When feeling fairly well they forget the physician's advice and warning. They seem able to borrow from themselves to-morrow's energy. They will be the soul of a party one day, ending up with a night at the theatre—the gayest of the gay. Next day is spent in bed, in a darkened room, with a racking headache, the brow contracted with pain, begging to be left alone in their misery—the saddest of the sad. At other times they will awake with a sharp headache, improve as the day goes on, and dine out in the evening with a sense of enjoyment. Their friends and acquaintances cannot make them out, or understand them. They themselves always complain that they cannot do what other people do, and that they are not understood, and not unjustly. They are not as other people. Ardent, enthusiastic, capable of great self-denial, they are a race by themselves. They have played an active part in many modern movements.

Such persons, with highly developed nervous systems and small viscera—including an "insufficient" liver, which reverts to the uric-acid formation—are those who suffer from lithiasis and are dyspeptics. The presence of the uric acid seems to impair the gastric juice, as to its solvent properties. Sometimes the pain is experienced when the stomach is empty, and relieved by food. Here there exists a quantity of acid mucus in the stomach. An emetic gives great relief; squeezing the gastric wall and expelling a quantity of acid matter, Dr. C. J. Hare thinks. Hot water, all the better for containing a little potash or phosphate of soda, gives speedy relief. Hepatic stimulants, as ipecacuanha, euonymin, or taraxacum, steadily persisted in, raise the tone of the liver. Chloride of ammonium is often useful. An occasional mercurial pill, followed by a seidlitz powder, produces good results. If the stools are tarry, some podophyllin is indicated. For the lithiasis, lithia is the best uric-acid solvent, for these neurotics do not bear potash well. Phosphate of soda is their laxative. Some like Carlsbad salts.

As to food, they are not flesh-eaters. Animal food adds to the lithiasis. The food of the Patriarchs, "corn and wine and oil," is that best suited to them. Fish is permissible; fruit is very good for them. The sugar the cook adds to stewed fruit causes too much acidity with them. Well-prepared farinaceous matters are good. Milk puddings made without eggs are good. Cream is excellent. It can be taken with tea and coffee, or soda-water, or as creams—chocolate or other. So is cod-liver oil, especially if there coexist some lung-mischief. (I would strongly advise all readers of this article to narrowly watch the urine of their phthisical patients of the neurotic diathesis, and see for themselves how far lithates are present in it. Recent observations made at Victoria Park Hospital tell of old kidney-mischief in patients who have died of phthisis. In one case of mine the lung trouble had a history of four months, the interstitial nephritis being much older. In another lung case the constant presence of lithates caused me to pronounce for kidney-mischief. Both kidneys were extensively fatty, with adherent capsules. Prout wrote that the presence of lithates in organic disease were of evil omen. And one can readily understand that a system endowed with an "insufficient" liver, revealing its incompetence by falling back to the primitive uric-acid formation, and handicapped by old-standing interstitial nephritis, can make but a poor fight when assailed by disease.)

A very curious corroboration of what is written here about the food of these neurotics, at once dyspeptics and lithæmic, is furnished by the fact that while the wild dog is a flesh-eater, the highly bred pet dogs of to-day are quickly made ill by animal food. This fact was told me lately by an aristocrat (of the class discussed in this article), and on making inquiries it was found that this fact is well known to dog-fanciers. The collier of the north has the best of meat for his dog, even if he, his wife, and his children go without. But if the well-bred dog of distinguished lineage has meat three days consecutively he is manifestly out of sorts, and commences in the red mange, which it seems is eczema, a skin affection notoriously linked with gout. As the master is, so the dog is. The liver evidently is plebeian, and does not get on well with a patrician existence. Severe bodily exertion in the open air alone enables it to carry on urea-formation satisfactorily; or, in other words, flesh-eaters must be of active habits if they wish to avoid the uric-acid formation.

Lithæmic dyspeptics are very difficult persons to manage or treat satisfactorily, whether as regards their medicines or their dietary. Medicines are apt to disagree with them; vegetable tonics are apt to excite the vesical centres; iron upsets their liver; opium acts as an excitant rather than as a sedative. They, as a rule, dislike milk puddings; they love the sapid meat; they hate giving trouble, or having any food specially prepared for them. Anything which absorbs them makes them forget the physician, his counsel and his warnings. They throw themselves into everything with such *abandon* as leaves them no thought for anything else. Yet they are highly intelligent persons; and the female neurotic is commonly a very charming little lady. Some rustic neurotics are not *petite*, but they never are corpulent. George Eliot has a whole series of them in "Adam Bede"—the immortal Mrs. Poyser was one. I am not sure that Mr. Craig, the gardener, was not one too. When Mrs. Poyser was summing up that worthy she concluded, "It was a pity he couldn't be hatched over again, and hatched different." And a pronounced neurotic, well known to me, regrets frequently that Mrs. Poyser's suggestion cannot be carried out.

Civilization it would seem—like everything else in this imperfect world—is not an unalloyed good.

AN UNEXPECTED NEPHRECTOMY.—At a meeting of the Leeds and West Riding Medico-Chirurgical Society Mr. Hartley narrated a case in which, after beginning to operate with a view to draining an abscess in the iliac fossa, he successfully removed a tuberculous kidney (*The British Medical Journal*). The patient, a woman, aged twenty-four, three months after her second confinement, began to suffer from great irritability of the bladder, with polyuria. Six months before she came under Mr. Hartley's care, she became an in-patient of a hospital, when a swelling occupying the iliac fossa and the loin was aspirated, and afterward emptied of a large quantity of pus by a small incision above the centre of the iliac crest. For two months there was a copious continuous discharge of pus, and she fell into a condition of hectic and exhaustion so extreme that when she came under Mr. Hartley's care, in June last, it was doubtful whether she could bear any operative interference at all. In addition to a fluctuating swelling, about the size of a fœtal head, discharging fetid pus from the sinus left by the previous incision, there was felt above and behind it a hard irregular mass in the region of the kidney. A free incision was made, extending obliquely upward and backward from the sinus, evacuating about thirty ounces of very offensive pus. Upon passing the hand into the cavity, and introducing a finger through a sinus in its upper part, the kidney was found to be utterly disorganized. It was, therefore, stripped from its attachments and removed, the pedicle being transfixed and tied in three portions with stout silk; the ligatures were left long and brought out of the wound, which was left open from end to end to insure drainage. The temperature remained normal after the second day, the ligatures came away on the fourteenth, and at the end of two months the wound was healed.

THE TREATMENT OF CHOREA BY CEREBRAL REST.[1]

By J. LEONARD CORNING, M.D.,
NEW YORK,
CONSULTANT IN NERVOUS DISEASES TO ST. FRANCIS' HOSPITAL, JERSEY CITY, N. J.

MR. PRESIDENT: Before proceeding to the advocacy of any special plan of treatment, I conceive it incumbent upon the physician of to-day, not only to unfold his views in the light of the clinical statistics at his disposal, but also to show the relation of *what* he proposes to the morbid physiology involved. Forty years ago this essentially scientific mode of analysis would have been impossible. Living, however, as we do at the present time, amidst the conquests of inductive thought in all branches of the healing art, we find it quite out of the question to withstand those tendencies of the day which have given us a physiology, a pathology, and a pharmacology, built upon that foundation of all true science—the experimental method.

At the risk, then, of being accounted prolix, I shall endeavor to unfold the theme before us in a systematic manner, relying upon your good nature to pardon any shortcomings.

Definition.—The term chorea (χορεία, dance), or St. Vitus' dance, dates from the second half of the fourteenth century. At that time a peculiar pandemic disorder extended throughout the region of the Rhine and Moselle. During the prevalence of the disorder in 1418, it was the custom at Strasburg to lead those affected to the chapel of St. Vitus, that they might be benefited by religious ceremonies of various kinds. Hence the origin of the term.

Much confusion has arisen from the fact that very dissimilar groups of symptoms have been included under the designation. Thus we hear of a chorea magna or Germanorum, and of a chorea minor or Anglorum, not only among the older writers, but also those of recent reputation as well. For my own part I fail to comprehend the justice of what, to say the least, appears, from an etiological and clinical standpoint, but arbitrary grouping of symptoms. Indeed, as far as can be discerned by a careful analysis of the phenomena, it appears to me quite impossible to consider the manifestations known as chorea major as constituting a separate disease by themselves. In this matter I am quite in accord with Von Ziemssen, who considers chorea major as only the product of genuine psychoses and cerebral maladies on the one hand, and of hysteria on the other.[2]

In the following description, therefore, I shall only include such phenomena as are commonly comprised under the head of chorea minor. I feel compelled to take this stand in the face of the opinions of such observers as Steiner[3] and Bodo Wenzel,[4] not by reason of any preconceived opinions as to pathology, but after careful observations in the clinic and copious references to the literature of the subject.

Symptomatology.—There is nothing specially characteristic about the prodromata. The premonitory symptoms most frequently observed are derangement of memory, irritability, and inattention. As a rule, the irregular muscular movements first occur in the face, shoulders, and hands. Sometimes the inco-ordinate contractions are confined to one side or the body; whereas in a not inconsiderable number of cases the affection is general. The irregular contractions of the muscles give rise to grotesque distortions of the face, rotation of the eyeballs, strabismus, continual to-and-fro movements of the tongue, jerking of the shoulders, and contortions of the hands and arms.

The face of an individual suffering from a severe attack of chorea presents a veritable panorama of the emotions.

The forehead is darkened by a succession of frowns; the corners of the mouth are drawn down or from side to side; the eyebrows are depressed, and the tongue protruded spasmodically. Suddenly the repulsive picture is changed; the corners of the mouth are elevated; the eyelids are rapidly opened and shut; and the brow is expanded, so that the countenance presents the appearance of demoniac laughter. The inco-ordinate condition of the muscles which gives rise to this succession of contradictory facial expressions has been aptly termed "*folie musculaire*" by Broilland, and "insanity of the muscles" by Bellingham.[1] When the symptoms are confined to one lateral half of the body (hemichorea), disorders of speech are frequently observed. The latter are more pronounced when the right than when the left side is involved. In the less severe forms the muscular contractions are comparatively moderate; but in cases where the phenomena are intense, and the muscular system generally involved, even a moderate degree of co-ordination becomes almost an impossibility. Great difficulty is experienced by the subject in maintaining the erect posture; the limbs and body oscillate to and fro, so that to the eye of the casual spectator such an individual presents much the appearance of one laboring under the effects of intoxication. In aggravated cases the choreic movements continue during sleep, giving rise to obstinate insomnia, which serves to break down the general health of the patient and render his restoration to health a matter of great difficulty. Where, however, the type of disease is less severe, the choreic movements usually cease during sleep or under the influence of an anæsthetic. The irregular movements are much increased by any attempt on the part of the patient to execute voluntary movements, or when laboring under the effects of excitement. Thus, if asked to show the tongue, he thrusts it forth in a rapid succession of jerks. When attempts are made to speak the facial muscles become distorted, and the muscles of mastication are suddenly and violently contracted, so that the tongue and walls of the mouth are often severely bitten.

More or less disturbance of psychical function is observed in the majority of cases of chorea. The subject becomes depressed, irritable, and forgetful, and is not infrequently the victim of violent outbursts of anger. By an exercise of volition the patient is able, in many instances, to suppress the spasmodic movements for a short time. Unfortunately, however, the apparent amelioration is quickly succeeded by an aggravation of the phenomena; so that the conclusion becomes inevitable that such efforts of the will are productive of increased irritability. Disturbances of sensation are sometimes encountered in chorea. Anæsthesia of one-half or of the entire body is observed in some cases, whereas in others hyperæsthesia is present. In yet other cases pressure along the course of nerve-trunks reveals painful spots; and like exploration above the spinous processes reveals a similar state of things. Usually the general health is not materially affected, except, as already noted, in severe cases, where the sleeplessness and extreme irritability finally result in exhaustion of the vital resources of the organism.

Course, duration.—The course of the disease is generally chronic, usually lasting from five to eight weeks. Severe cases may, however, continue from three to five months. Where the disease persists for a series of years, the symptoms may be owing to organic changes in the central nervous system.

In the majority of cases the disease terminates in complete recovery. Where death occurs it is usually to be assigned to some intercurrent affection. Occasionally, however, a fatal termination results from the severity of the choreic symptoms themselves.

In cases where recovery takes place, an irritable condition is sometimes observed to persist after the choreic symptoms have completely disappeared. Partial recovery is not frequent. In rare cases, however, profound mental disease or paralysis succeeds the primary affection. Death is comparatively rare among children, where there are no complications.

Etiology.—It has long been known that hereditary predisposition plays a prominent part in the development of functional disturbances of the central nervous system, and chorea constitutes no exception to the rule. The susceptibility to hereditary influences applies with special force to the co-ordinating centres of the motor apparatus. Those in whom prenatal causes have conspired to develop neurotic tendencies exhibit a peculiar susceptibility to the influence of external stimuli; they are irritable, fidgety, and easily aroused to anger by even the most trivial causes. As children, such individuals frequently excite great expectations, on account of a peculiar precocious endowment which lends plausibility to the assumption that they are possessed of unusual intellectual capacity. It is only, however, as the years of adolescence are attained that the futility of such hopes becomes apparent, and friends and guardians are reluctantly compelled to abandon the dream of greatness which, but a few short years before, they had almost looked upon as an accomplished fact.

Sée[1] has found that about one-third of the cases occur between second dentition and puberty. The same author has also found that three-fourths of the cases admitted to the Children's Hospital at Paris occurred among girls.

An endeavor has been made by several writers to exhibit the relationship existing between chorea, cardiac troubles, and rheumatism.

Todd and Addison have recorded cases in which chorea was associated with heart trouble, while Money[2] and others have adduced statistical evidence to show the relationship existing between chorea and rheumatism. Against the theory of this pathological relationship Steiner, of Prague,[3] has collected statistics, from an analysis of which he shows that, among over two hundred and fifty cases of chorea, only four occurred during the actual course of acute articular rheumatism.

The exact nature of the relationship existing between chorea and rheumatism is, therefore, by no means positively ascertained, though that in a considerable number of cases the pathological pictures of the two diseases are associated in some manner seems beyond question.

The occurrence of chorea after scarlatina has been noted by Trousseau; but of the more intimate pathological relation of the two diseases we know little.

Among the more prominent exciting causes of chorea may be mentioned: Sudden fright, protracted intellectual exertions, combined with worry; thus, I have seen choreic symptoms induced in neurotic school children, where there was a history of overwork combined with fear of punishment. A discontented, fidgety disposition of mind constitutes a favorable condition for the development of chorea. It has long been known that the persistent imitation, by apparently healthy children, of the contortions and grimaces of those affected by chorea, frequently results in the development of the disease. Phimosis, and other forms of peripheral irritation, may perpetuate choreic symptoms, and the same may be said of certain eye-difficulties. Where there is no predisposing neurotic factor involved, however, difficulties of this kind may exist without giving rise to symptoms.

Nevertheless, where peripheral difficulties exist conjointly with chorea they should be removed.

Pathology.—The data afforded by experimental observations and *post-mortem* investigations are not decisive. Still, though it is impossible to confirm those mathematical conceptions respecting the nature and location of the lesion frequently entertained, it is, nevertheless, quite within the range of possibility to form approximate conclusions as to the portions of the nervous system in which changes *may* result in the production of choreiform convulsions.

[2] Brain, vol. v., 1882–83.

[3] Vjsche, Bd. iii., 1868.

Thus we know that when, as in Chauveau's experiments, the influence of the brain is eliminated by division of the cord below the skull, choreic movements may continue.

We also know, from the experiments of Legros and Onimus, who succeeded in arresting choreic convulsions by division of the posterior cornua, that choreic movements may emanate from that region of the cord.

Adding these results together we may say then, first, that choreiform movements may come from the cord, and secondly, that their seat, when they thus originate, is in the gray matter, and very probably in the posterior gray matter.

But, on the other hand, we know from the experiments of Rosenthal and others that choreic movements may be engendered by irritation of the gray matter of the brain, and more particularly of the basal ganglia and cortex.

In addition to this experimental knowledge, we have learned from clinical observation that, in the majority of cases of chorea, there is more or less mental disturbance. Now, since by common consent the agency of the cortex in the evolution of mental phenomena is conceded, we are justified in believing that in most cases of chorea we have indeed to do with an implication of the cerebral cortex.

Again, since the majority of cases of chorea recover under appropriate treatment, the lesion with which we are concerned is usually, in all probability, functional in character, consisting in some minute nutritive change of the protoplasm of the ganglia.

There is no logical jugglery about this pathology; for, if it be utilized as the basis of practice, experience proves that the results attained are in all respects satisfactory.

Finally, there is a small percentage of cases in which the hyper-irritability extends to the gray matter of the cord. These are the patients who are helped by calabar bean and cold applications to the spine. In a relatively insignificant percentage of cases, as shown by Elischer, Lockhart, Clark, Dickinson, and others, there is also organic disease. Of course, where such is the case, little of permanent value can be anticipated from any form of treatment.

Treatment.—The first indication which must be met is to allay the condition of cerebral erethism which is such a constant accompaniment of chorea.

If the child is at school, she should at once be removed; and even the milder kinds of intellectual work should be strictly prohibited. But these measures, though good enough in themselves, are rarely sufficient to overcome the evil already accomplished. To arrive at satisfactory results, we must afford complete rest to the exhausted and irritated ganglia. In other words, we must induce sleep, and by prolonging the state of unconsciousness to suit the morbid exigencies, enable those reparative processes to transpire in the ganglia which are essential to the complete functional restoration of the cell. The great factor in the successful treatment of this class of cases, then, is rest—perfect, undisturbed tranquillity of the thinking apparatus—not the limited amount of rest suited to the healthy brain, but a quantity greater in proportion to the degree of morbid deterioration. By prolonged sleep it is possible for the ganglia to hoard up an amount of energy proportionate to the duration and profundity of the sleep itself, or, in other words, in the ratio of the reduction of the daily output of brain-energy. Thus by slow degrees the proper correlation between integration and disintegration may be re-established. It is useless, however, to hope for any permanent results at once, for, when the perverted nutritive conditions have once become established, nothing short of prolonged rest can by any possibility result in the re-establishment of the normal nutritive processes of the cell-economy.

Where the function of sleep is affected, as it is in many cases, it is impossible to increase at once the amount of rest to a sufficient extent to meet the demands of the morbid cerebral condition. Nevertheless, by gradually increasing the duration of the sleeping period, it eventually becomes possible to afford the patient an amount of rest sufficient to neutralize by slow degrees the condition of irritation and exhaustion. The bromides should be given during the day in cumulative doses, in order to allay the condition of irritability, and to cause a progressive decline in the mental manifestations as the hour for complete repose approaches. There should be no hesitation in employing sedatives, but always with the understanding that their use is only a measure of temporary expediency.

The most difficult class of cases to manage is that in which there is present some stomachic weakness precluding the possibility of any considerable medication, and necessitating a more or less protracted discontinuance of treatment from time to time.

Where such digestive difficulties exist, no attempts at profuse medication should be made, at least not until the tolerance of the stomach has been largely increased by appropriate means. With the present resources at our command, this problem is much easier of solution than it would have been even ten years ago.

And here let me add a word respecting the method by which I seek to practically carry out the above principles of treatment, to wit: 1, Cerebral rest; 2, increased general and cerebral nutrition; 3, elimination of psychical irritation, and removal of peripheral irritation, particularly that engendered by light and sound.

The subject is secluded in a darkened room from ten to fifteen hours at a time, according to the amount of sleep which it is desired shall be had during the twenty-four hours. The amount of sleep is *progressively* increased by habit, moderate medication, and hydro-therapy, and no attempt is made to produce a sudden state of stupor by the reckless use of sedatives. When the patient awakes, as is usually the case, two or even three times during the hours set apart for rest, nourishment is administered, but always in a fluid and easily digested form. Where difficulty is experienced in again falling asleep, resort is had in the beginning to limited medication. The few hours of wakefulness are devoted exclusively to some form of amusement—reading, writing, and even the mildest forms of mental concentration being absolutely prohibited. This, in brief, is the method from which I have already seen most happy results, and from the employment of which I hope and believe much good will in future be derived. It is hardly necessary to say that the problem of cerebral rest is essentially different from and presents many more difficulties than spinal rest, as described in the earlier edition of Weir Mitchell's book. To give repose to the motor cells of the cord is comparatively an easy problem, and one which only exacts a permanent fixation of the motor apparatus for its solution, the consciousness or unconsciousness of the individual being only a matter of secondary importance. Rest, however, for those cells the function of which is the evolution of mind, can only be obtained by a prolonged period of absolute unconsciousness; and this, as a matter of course, will often tax the patience and resources of the physician to the utmost. Perseverance and the utilization of the principle of habit will usually, however, render essential assistance.

In conjunction with this system of rest, the Turkish and vapor baths may frequently be employed with advantage.

Having at length by these measures reduced the condition of cerebral erethism, alteratives may be given. At one time the sulphate of zinc was given very largely in chorea; but of late years the preparations of arsenic, which seem to exert almost a specific influence, have driven it more and more into the background.

In giving arsenic it is usually well to carry its administration up to the point of toleration. At the present moment I have a boy of fifteen under treatment, who is taking eighteen drops of Fowler's solution three times a day, without apparent detriment. The case is one of three years' standing, and the patient, a precocious, neurotic, and undersized boy, has been in the hands of various physicians.

I at once put him upon a course of thorough rest, prescribed forty grains of the bromide of sodium a day, removed him from school, and prohibited animal food, substituting for the latter a farinaceous diet with milk. This farinaceous diet was, however, only continued *for a short time*, till the cerebral erethism had disappeared.

Six weeks have now elapsed since I first began treatment. The irregular movements which were located in the left side of the face, extending to the shoulder and hand of the same side, have now ceased altogether, and only when excited or startled do they reappear. This case will, in all probability, make a complete recovery; but I shall not allow him to return to school, or to indulge in violent exercise of any kind, for fear of a relapse. At present his appetite is good, and he is taking large quantities of nitrogenous food.

In this, as in many other cases, I employed simultaneous galvanization and refrigeration of the head in the beginning of treatment.

As this is a useful mode of allaying the irritability under which these patients labor, I will describe it. A stout band of india-rubber webbing is first secured around the head, so as to interrupt the circulation in the scalp. An electrode of sponge, provided with a hollow chamber of tin, is then connected with the positive pole of a galvanic battery, and placed upon the head. The chamber is then filled with ice-water (not ice), and the negative pole having been placed in the neck, the current is made, and treatment continued for half an hour. Sometimes I still further enhance the efficacy of the procedure by the application of compression to the carotids (by means of my mechanical compressor).

Quite striking effects are sometimes observed immediately after the cold begins to make itself felt, which, of course, occurs rapidly on account of the suspension of the circulation in the scalp, by which the transmission of the cold to the cortex is greatly facilitated. Thus, some months since, I had a little girl under treatment for choreic spasms of the face. These, though not excessive, were obstinate in character, and did not yield readily to arsenic; and yet, when the above application had been made for about ten minutes the spasms invariably entirely disappeared, and remained absent as long as the treatment was continued, and sometimes for an hour afterward.

When the combined sedative action which the galvanic current and the ice exert upon the cortex is borne in mind, such prompt effects are, perhaps, not to be wondered at. To the child and his parents such results appear little short of marvellous, and the spirit of hopefulness thereby engendered constitutes a helpful factor in a protracted course of treatment.

Finally, it is well, at least in the early part of treatment, to confine the patient to a strict farinaceous diet, which, in chorea as in epilepsy, will form a helpful adjunct to treatment.

These in brief are a few of the salient features of that mode of treating the affection which I have found most efficacious in practice.

26 West Forty-seventh Street.

Manuscript in Rolls.—Contributors who honor us with their communications would confer a great favor if they would send their manuscript folded and not rolled. A voluminous manuscript which has been rolled up for a long time is a most unmanageable thing.

PUERPERAL FEVER FROM VARIOUS CAUSES.

By W. D. SCHUYLER, M.D.,

NEW YORK.

The following cases are offered as illustrations of the belief that puerperal fever may arise from various causes, and that the preventive treatment of this disease cannot be said to be complete when it aims only at the prevention of septicæmia.

There are other forms of puerperal fever than the septicæmic said to arise from or originate with the parturient act, and it is believed that these cases substantiate that view.

These cases, and other easily obtainable facts, illustrate that there are several forms of puerperal fever. There are the contagious, the septicæmic, the malarial, the phlebitic, and the pyæmic. Of these there are sub-varieties, and we have the metric, the perimetric, the endometric, and the vaginal, and preventive treatment must include the recognition of the several varieties and sub-varieties and their causes.

As a point of special interest I would direct attention to the fact, illustrated in one of the cases submitted, that it is not safe to puncture deeply through comparatively sound tissues for the relief of mammary abscesses; it is better to delay opening them until they point somewhere near the surface.

Again, I would direct attention to the fact that syringing the cavity of the womb is not so dangerous a procedure under the circumstances, in cases like those related, as it has by some been regarded.

My method is to place the woman in the Sims position, elevate her buttocks, and place a shallow bowl so that it will catch all returning fluid. I then introduce my self-retaining speculum, which dilates the cavity quadrangularly when opened, and discloses not only the cervix but the entire vaginal cavity. In this way I am enabled to judge of the exact locality of the trouble. If the uterine cavity is to be syringed, I introduce into it, one after the other, two No. 10 or 12 soft French prostatic catheters, and then with a head-mirror, if the light be insufficient, throw reflected light upon the whole field, which enables me to see all the parts, to know exactly what is being done, and what are the results. For washing out the uterine cavity I use Davidson's syringe, throwing the disinfecting fluid first through one and then through the other catheter, and continuing the process until the liquid which returns indicates that the cavity has been thoroughly cleansed and disinfected. This procedure I repeat as often during the twenty-four hours as the requirements of the case indicate.

Case I.—*Puerperal fever.*—Mrs. F. A. J——, aged thirty, multipara and healthy. Was taken in labor, December 25, 1886, at 3 A.M. Under the care of an experienced midwife. After nine hours of moderately severe pains she was delivered naturally of a female child. The midwife reports that the secundines came away shortly after the delivery of the child, and the womb contracted into a hard, round form.

On the day following the patient felt well, but did not, however, rest quite well that night.

Monday, second day after labor, at noon, the milk came in rapidly, filling the breasts full During the morning the patient was out of bed for ten minutes; after that she had two movements of the bowels. On Monday night she did not sleep at all.

On Tuesday, third day, she had a chill in the forenoon, followed by fever, which continued, and in the evening I was asked to see the patient. Found her with a flushed face, somewhat restless, severe headache. Pulse, 120; temperature, 103½° F.; tongue coated. No pain in abdomen; no trouble with water. Ordered aconite, potass. brom., potass. iodidi, M., with directions to be given every two hours until headache and fever abated. Bowels not moved to-day.

Fourth day, Wednesday, 9 A.M.—Patient feeling very much better. Headache passed off; is less restless. Pulse, 80; temperature natural (98½° F.). Treatment continued in fractional ($\frac{1}{30}$) doses. At 4 P.M. fever had returned; pulse, 120; temperature, 102½° F.; headache, but not so severe as yesterday. Ordered a cathartic and the continuation of the sedative and alterative febrifuge.

Fifth day, Thursday, 9 A.M.—Had a bad night, with quite a high fever, which abated somewhat after 1 A.M.; vomited and had pains in the abdomen, probably due to the cathartic, which caused three actions of the bowels, the second being quite free, and all being liquid. Pulse, 100 to 160. Lochia absent since yesterday. Secretion of milk diminishing; abdomen only slightly tender; no tympanites. Water scanty, but passes without pain. Uterine temperature not higher than the general temperature as taken in the axilla. In the absence of other or, especially, of uterine indications, and following the indication of the febrile manifestation, I ordered three five-grain capsules of quinine to be given before 2 P.M. At 2.30 P.M. I found the patient with no fever; pulse, 100; temperature, 98½° F. Abdomen natural; no pain or discomfort in its lower portion; no scalding of water. Advised no treatment, but to give the aconite and potash if the fever returns. At 9 P.M. patient's face is flushed; says she feels well, but the thermometer registers 103½° F. in the axilla, and pulse is 120. Though not ordered, she took four (five-grain) capsules of quinia during the day. The lochia continue, though scanty, and are not of a bad odor. The bowels have been troublesome to-day, having moved every hour or oftener, the movements being preceded by pain; stools very dark, and liquid. Ordered bismuth and Dover's powder.

Sixth day, Friday.—Patient reports she had a good night, that fever abated after my visit last evening. Bowels are checked, no abdominal pain, and urination is not painful. Pulse, 86; temperature, 100°F.; ordered quin., gr. x., at 9.30 and 11.30, and gr. v. at 2 P.M. At 3.30 P.M. took quinine as directed, but fever has come on notwithstanding. The lochia were absent and the secretion of milk ceased. From this time until the *tenth* day the pulse varied from 84 to 124, the temperature fluctuated between 100° F. and 105⅖° F., and the bowels continued irritable.

On the tenth day, having become convinced that malaria was not the cause of a fever manifesting such an irregular course—although the absence of local symptoms excepting the bowel-trouble seemed to justify such an opinion—I decided to explore and tentatively wash out the uterine cavity, and proceeded to introduce a large, soft No. 14 (American scale) catheter, the patient lying in her usual position on her back in the bed. The os was found far away, well back against the posterior vaginal wall, and the instrument was introduced with some difficulty, but as it entered the uterine cavity I was surprised by a gush of serous fluid which struck well up upon the sleeve of my undervest. I proceeded then to syringe the cavity with disinfected hot water, with a hard rubber syringe, such being the only one at hand that would operate. The syringing, which was interrupted to allow of a frequent discharge, brought away a quantity of hemorrhagic and grumous fluid and some blood-clots. Shortly after the syringing the temperature again rose to 105° F. I ordered potass. iodidi, gr. x.; liq. ammon. acet., gtt. x., M., ft. sol., every hour until I should return, and left the patient. The patient's statement was that she had had a very bad night, she was so hot. Her face was flushed but worn, the pulse soft and uncertain. It was counted with difficulty; just before I left her, at 5.30 A.M., it was 128. At 9 A.M. pulse had fallen to 92; temperature was 102° F. Had taken three doses of the potass. iodidi mixture (gr. xxx.); ordered it continued in the same dose every hour. At 9 P.M., pulse, 84; temperature, 98⅗° F. Bowels loose and give patient some discomfort, but otherwise feeling well. Has taken gr. x. quinine. Catheterized the uterine cavity, and again washed out a quantity of bloody grumous fluid and clots. After operation the thermometer registered 99½° F.; no lochia.

Wednesday, January 5th, 9 A.M.—No fever. Bowels moved four times in the night. Bismuth powders were given. Quinine and iodide of potash continued. 8.30 P.M.: Pulse, 108; temperature, 102° F.; catheterized uterine cavity.

Thursday, January 6th.—Messenger called me at 7.30 A.M. Report was that she had had a bad night, and that fever was quite as high as two nights before. Patient's appearance much worn; face flushed, lips blue, tongue coated, dry; pulse soft, uncertain, 120; temperature, 102° F. Bowels still troublesome. Stools very dark liquid. No lochia. Treatment continued with pot. iod., and bismuth powders. 10 A.M.: Pulse, 120; temperature, 103½° F. Put the patient in the Sims position, dilated the vagina with my speculum, and syringed uterine cavity thoroughly and evacuated a large amount of grumous hemorrhagic fluid. Temperature not changed by syringing. Advised waiting for two hours. 2.30 P.M.: Patient easier. Had been given one dose of the iodide mixture, and one bismuth powder. Pulse, 108; temperature, 100⅗° F. Ordered all treatment discontinued until further directed. 10 P.M.: Pulse, 92; temperature, 100° F.; syringed uterine cavity again, and removed a comparatively large quantity of hemorrhagic and necrotic fluid. Bowels less troublesome.

Thirteenth day, Friday, 7.30 A.M.—Pulse, 84; temperature, 98½° F. 10 A.M.: Pulse, 92; temperature, 100° F.; syringed uterine cavity (putting her again in the Sims position and bringing the uterine os into view with my speculum), and washed it out thoroughly for the second time, removing a large quantity of fluid containing blood, detritus, and clots. After syringing, the temperature was found ⅞° F. higher. Treatment by medicine still discontinued, and broths ordered. 3 P.M.: Pulse, 84; temperature natural, fallen from 100⅞° F. Bowels somewhat loose since yesterday. There are no natural lochia. Patient looking better. 10 P.M.: Has no fever; syringed uterine cavity.

Saturday, January 8th, 9.30 A.M.—Pulse, 76; temperature natural. Slept nearly all night. Has some appetite for the first time during sickness this morning. Lochia are reappearing naturally. Strength of pulse good. Washed uterine cavity and ordered a generous liquid diet. 2 P.M.: Patient is not so lively, but has no fever. Treatment limited to attention to diet. 8.30 P.M.: Patient has a tired feeling, and the appetite she felt yesterday has departed. Pulse, 84; temperature, 99½° F.; syringed uterine cavity—patient in Sims position—and ordered tinct. ergot., ʒ ss., with drop-doses of tinct. ipecac. and liq. fer. persulph. and gtt. ij. tinct. opii; two doses during the night and one in the morning, to prevent uterine relaxation and possible septicæmia. Bowels now moving naturally.

From this date on no special event occurred. The uterine cavity was syringed daily, and on January 14th there was no fever, the patient's appetite was improving, her bowels were moving regularly, and she was convalescent.

CASE II.—*Malarial puerperal fever.*—Mrs. G. L——, aged thirty, and a multipara, was taken in labor November 14, 1884, which continued and terminated normally at the end of thirteen hours. The uterus contracted firmly, and the condition of the mother and child was good. The child was a well-developed, healthy-looking girl.

The condition of the mother remained favorable until November 15th, when she was unable to pass her water, and it was drawn with the catheter. On November 16th she complained of severe pain in the abdomen when she coughed. On the 17th she felt cold early, and afterward was feverish. At 9 A.M. her pulse was 132; temperature, 102½° F.; she had headache, pain in the back, her tongue was coated, the abdomen was somewhat swollen and tender to touch. Coughing causes severe pain in the abdomen. Lochia natural. Bowels had not moved, and an injection was ordered. The urine, drawn with the catheter, was normal in color and odor. At 5.30 P.M. the pulse was 136; temperature, 102° F.; and cough under control by the anodyne mixture prescribed in the morning. Headache. Lochia natural. Has urinated naturally.

On November 18th the patient said that she was better, and was having her hair combed. A large quantity of gas escaped from the bowels, and the water was passed naturally. But her pulse remained at 124, with a temperature of 102° F. Tongue moister and less brown than yesterday. Abdomen swollen and tender. Bowels inactive. Ordered castor-oil and syrup of buckthorn. Lochia have more color and a foul odor.

Ordered ergot and nux vomica in small doses, to maintain tonic uterine contraction for the purpose of preventing possible absorption of septic material from the uterine cavity. Turpentine stupes, also, were applied to the abdomen.

At 8.30 P.M. the pulse was 120, and the temperature 100° F. Water passed freely and bowels moved slightly. No headache.

At 8.30 A.M., November 19th, the patient's face was flushed, her tongue was brown and dry; pulse, 132; and temperature 104° F. Lochia less abundant. Bowels moved freely in the night, and the secretion of milk increasing.

At 2 P.M. the fever was increasing; pulse, 140; temperature, 104½° F.; abdomen swollen and tender. Syringed the uterine cavity, but did not remove any considerable amount of morbid material. Uterine temperature no higher than the general temperature.

The conditions found did not confirm a local causation for the febrile state. Ordered hot applications to the abdomen, and the bromide of sodium, iodide of potassium, and aconite mixture to be continued.

8 P.M.—Fever somewhat abated. Pulse, 120; temperature, 101° F. Ordered gr. iv. quinine, gr. ⅕ of opium and ipecac, M., in capsule, every two hours, beginning at once and continued through the night, unless fever again exacerbates.

November 20th, 9 A.M.—Temperature, taken during the night every two hours, averaged 99½° F. Patient looks better, and has little or no abdominal pain. Considering the quite normal condition of the womb and, on the other hand, the daily remittent character of the fever and the fact that there was a stationary wash-basin in the room which was not free from an unpleasant odor (although the house was kept seemingly in the most wholesome state of cleanliness and order), with the additional fact that the patient had suffered from malarial poisoning the previous summer, led me to conclude that the fever, although distinctly peritoneal (inflammatory) in manifestation, was due to malaria, and so to continue the treatment by quinine. At 8 P.M. the pulse had fallen to 108, and temperature to 100½° F., and the patient was easier in every way. She had taken twenty-eight grains of quinine since previous night.

November 21st, 9 A.M.—Patient feels better this morning. Has taken twenty-four grains of quinine during the night. Pulse, 100; temperature, 99° F.; tongue moist, and partially covered with a white fur. Abdomen is tympanitic throughout upper half, painful over lower, most marked on left side. Lochia scanty; water retained and was drawn with the catheter. Ordered cold applied over lower part of abdomen. No quinine to be given to-day. 10.30 P.M.: Pulse, 108; temperature, 99½° F. Apprehensive of another rise of temperature I ordered sixteen grains of quinine to be given during the night. The bowels were moved by an injection.

November 22d, 10 A.M.—Report is, the patient had a good night. Looking very well this morning. Enemata administered caused only a slight evacuation from bowels. Water had to be drawn during the night. Pulse, 96; temperature, 97½° F. Tongue large and red, not coated. Skin cool and moist. Abdomen softer, but still somewhat tympanitic. Is not tender, and even deep pressure causes little pain. Tenderness is felt when pressure is being removed. Deep breathing is not painful; temperature and pulse indicate the need of stimulants.

On November 23d the fever had returned, and at 10 A.M. the patient's temperature was 104¼° F. There were tympanites and some abdominal tenderness. The bowels were moved with an injection. Quinine was added to the stimulants and external application of heat.

On November 24th the temperature began to rise at 7 A.M., notwithstanding the quinine, and at 8 A.M. the patient had a slight chill; at 10 A.M. her temperature was 104.5° F. Abdomen soft, and painful only when patient coughs. At 2 P.M. syringed the uterine cavity, but very little was washed away, and the temperature was unaffected by the washing. Bladder emptied with the catheter. The urine had a specific gravity of 1.018, and did not contain albumen. Ordered quinine. Tympanites and tenderness in the evening.

From this date until December 7th, the twenty-fifth day, the case went on with fluctuating temperature, tympanites, tenderness of the abdomen on pressure, and pain. Bowels were slow, and required enemata, and the catheter was used as occasion required. The uterine cavity was syringed daily, and quinine and stimulants were administered according to indications. Lochia scanty most of the time. On one occasion the patient's condition was made worse by the uterine washing. On the twenty-fifth day the case was dismissed, subject to call.

Comments.—The prominent pathological features of this case as manifested, were: A puerperal remittent fever and a concurring peritoneal inflammation or marked congestion, the considerable height to which the fever exacerbated and the profound character of the remissions, as denoted by the low temperature reached; the absence of marked uterine and also of septicæmic symptoms; the subjection of the fever principally, and ultimately wholly, by quinine; the depression of temperature after administering quinine in the moderately substantial doses given; the concurrence of atony of the bladder with depression; and lastly, the persistence of a low bodily temperature during convalescence and after quinine was discontinued.

The peritoneal complication was at first possibly excited by the irritant concussion of coughing, which the patient had been greatly troubled with for two weeks prior to the occurrence of labor, which entirely ceased during that act and for the day following, but which returned the next day, and which she then described as distressing, and felt mostly in the abdomen. It is even possible that but for this exciting cause this manifestation might not have developed with the occurrence of fever. Yet it is noticeable that it exacerbated and remitted concurrently with those actions of the fever, and hence may have been essentially due to the febrile (puerperal) cause. At no time, on the other hand, during the progress of the case did the uterine conditions, *i.e.*, the nature of the lochia or their retention, the condition of the womb, as regards a state of metritis, or an endometritis, or a condition of uterine relaxation that would favor reabsorption of fluids from its cavity, indicate that the peritoneal involvement, or the cause of the fever, was due to local conditions of or within that organ. Hence we must seek other than a uterine causation of the malady. The absence, also, of any morbid mammary manifestation would exclude the remaining possible local causation for the disease, which then must rest upon some infectious constitutional state. Septicæmia resulting from post-partum conditions as a cause of constitutional infection is to be excluded upon the grounds given, which furthermore exclude all sources of an autogenetic infection, and which therefore must arise from without. The sources of an exogenetic infectious cause are *contagion* from some other existing puerperal-fever case, also malaria. The latter may be contracted from swamp-miasm, or from decomposing organic sewage materials.

Contagion as a causation in this case is to be excluded (*a*) upon the general ground that no other existing case of puerperal fever was known of either by the patient, her friends, or by myself, and upon the fact that the patient had kept to her room very closely, facts which would render exposure most doubtful, and (*b*) upon the special ground that the course manifested by the fever was unlike that caused by contagion.

On the other hand, that a *malarial* infection was the cause is clearly shown by the distinctly remittent character both of the fever and of the peritoneal manifestation; by the fact of its control and final suppression by quinine, and finally by a history of malarial disease the previous summer.

CASE III.—*Pyæmic puerperal fever developed after lancing an inflamed breast.*—Mrs. R. A——, a multipara, aged thirty, was well up to the beginning of her labor, which came on, March 18, 1884, at 10 P.M., and was completed naturally in four hours. Her breasts began to fill on the 20th. On the 22d she had a chill, and her left breast became inflamed. Nine days afterward her attending physician lanced the breast, and pus discharged freely. He lanced it again on April 2d, and also April 5th. The fever continued, and on the 11th the patient had a severe chill, which was followed by irregular chills and fever daily with discharge from the wounds. During this time the patient was nervous, slept badly, had no appetite, and vomited all she took. Had pains in the gastric region, but bowels moved daily. An erysipelatous redness developed on one of her legs, and there was a somewhat enlarged gland in the popliteal space, but these developments did not amount to much; there was also an enlargement in left axilla. Fever and chills continued day after day, the chills occurring mostly in the afternoon. Lochial discharge was at no time very abundant, and soon ceased. Her water was passed regularly, and she had no abdominal symptom beyond vomiting and some general discomfort.

Forty-one days after confinement I saw the patient for the first time. She had recently had a chill, and felt cold, although her axillary temperature was 102.5° F. Her left breast was indurated and was slowly discharging pus from one of three incised wounds, two of which were gaping and were of considerable depth through the gland-tissue; her left arm was swollen; the side of the neck was also involved.

From April 29th to May 4th the general condition of the patient did not change materially, the pulse ranging from 120 to 132, and the temperature from 100° to 103° F. The arm, however, became greatly swollen; from the axilla down to the middle it had a boggy feel, and was very sensitive to pressure over the basilic vein, which was hard to the touch.

The womb was well contracted and the vaginal canal was free from morbid action. The urine contained no albumen and had a specific gravity of 1.010; bowels inclined to be constipated. From this date to May 9th the general treatment consisted in the use of tincture of iron, iodide of potash, chloride of ammonium, and carbonate of ammonia, with cod-liver oil and quinine.

May 13th.—Pulse, 116; temperature, 100° F. Arm less swollen, and less painful to pressure; hand less œdematous; hardness on inner surface is giving way; tongue clean, but dark red; bowels moved last night; water scanty. P.M.: Has taken twenty grains of quinine to-day; pulse, 120; temperature, 100° F.

May 14th.—Appearance improved. Very little discomfort now in throat; stools and water pass naturally; pulse, 108; temperature, 100° F. Has some appetite, and the swelling of arm and œdema of hand are diminishing.

May 24th.—Pulse, 104; temperature, 99° F.

May 25th.—Sitting up in a chair. Pulse, 100; temperature natural. Hand and arm quite natural.

June 2d.—Patient doing well; appetite good. Is sitting up every day. Pulse remains small.

In this case we have for consideration the following facts: The second day after a natural labor, occurring on March 18th, the breasts began to fill with milk, and on the fourth day the patient had a chill and the left breast became inflamed. Nine days after, the inflamed breast was lanced, and discharged freely; two days later it was lanced again, and three days later still it was lanced for the third time. Six days after the last operation the patient had a hard chill, followed by fever. After this she had a chill and fever every day (although she was at all times subjectively cold), and the wound in the breast continued to discharge until I saw her on April 28th, forty-one days after her confinement, at which time she had a pulse of 132, and a temperature of 103° F. She had just previously had a hard chill. Her breast was slowly discharging pus through one of the wounds, which was gaping, of considerable depth, and had a pale, meaty appearance. Her left arm, on the same side, was then swollen. On the second day after my first visit she complained of a fulness about the lower part of the neck and beneath the sternum on the left side, which rendered her breathing difficult and impaired her deglutition. Her mind was inactive. From this time on she had a feeling of fulness extending outward under the left clavicle, and at length making its appearance on the inner side of the arm, in the axillary space, where it was found later to be an implication and swelling of the basilic vein. This action did not cease until it had travelled well down into the median and anterior and posterior ulnar on the anterior and inner surfaces of the forearm. As a result of this swelling, which evidently was a phlebitis of the internal mammary vein, the left innominata, left subclavian, axillary, and basilic, there was a diffused hardness along the course of the veins, swelling and œdema of the arm, forearm, and hand. In the beginning of the process, and while the left innominata was involved, preventing a normal return of venous blood from the brain on that side, there was mental hebetude, and throughout there were chills and fever.

The case is clearly one of puerperal fever, due (1) to mammitis, and (2) to a resulting pyæmia and phlebitis, and had no causal relation to a deranged uterine condition or to a septicæmia arising from parturient results in that organ. The teachings it affords, are: (1) That puerperal fever is not necessarily septicæmia; and (2) that pyæmia and very grave constitutional results may occur from lancing a deeply seated mammary abscess, unless such can be done at a dependent point where free and complete drainage can easily be secured.

CASE IV.—*Puerperal fever from retained placental membranes after an abortion occurring between the fourth and fifth months of gestation.*—Mrs. D. A——, aged thirty-seven, multipara, had an abortion produced. The fœtus was expelled October 12, 1875, but the membranes and placenta were retained. On account of the latter I was sent for. On arriving I made a digital examination, and while I could feel the placental ball I was unable, on account of the contracted condition of the uterine os, to get far enough around it to effect its removal. The uterus was too small to admit my hand, and having no placental forceps with me I decided to leave the membranes and trust to their being expelled later.

On the day following the patient had some pain in the lower part of the abdomen and was feverish, the pulse being 120 and the temperature ranging from 103½° F. in the morning to 102° F. in the evening. The next day, the 14th, patient was more comfortable, the pulse and temperature being each 100° F.; the 15th, patient had some headache; the 16th, patient much better; pulse, 92; temperature natural; the 17th, 18th, and 19th I did not see her. The report was, she was quite well and was up in her chair. October 20th: While sitting up this morning she had a chill followed by fever. I saw her at 8 P.M., found her with high fever; pulse, 120; temperature, 106° F. The membranes had not been expelled. I ordered a cathartic powder, and a mixture containing aconite and liquor ammoniæ acetatis as a febrifuge.

October 21st, A M.—Bowels acted and she was relieved; pulse, 84; temperature, 99° F. 10 P.M.: Sent for. Patient had a chill at 9.30; found pulse 120; temperature, 103° F.; continued sedative mixture (bromide and chloral).

October 22d—Patient had a very good sleep after one o'clock in the morning. 8 A.M.: Pulse, 120; temperature, 101½° F.; evening temperature, 106.5° F. Knowing the membranes were retained, and as there was no lochial discharge there was no further question as to the cause of the fever, especially as the patient had been in excellent health previous to the occurrence of the abortion, hence the indication was to empty the uterus; and that failing, to keep it well disinfected internally and in a state of tonic contraction. To meet the latter indication I prescribed ergot, and for the former I resorted to disinfectant syringing according to the mode already described in Case I.

At 9 P.M. Dr. N. C. Husted saw the patient with me, and advised curetting the uterine cavity, which he proceeded to do, but brought away scarcely any membrane. After the curetting I again injected the uterine cavity, and then ordered gr. vj. quinine every two hours, with the liq. am. acet. and sedative mixtures.

October 23d, 7 A.M.—Patient easy; took during night gr. xxiv. quinine. Pulse, 104; temperature, 103½° F. 2 P.M.: Pulse, 100; temperature, 99° F. Perspiring and is easy.

October 24th, 9 A.M.—Patient had a good night; looks very well. Pulse, 84; temperature, 100° F. Syringed the uterine cavity.

October 25th, 9 A.M.—Had a good night; looks refreshed. Pulse, 100; temperature, 101½° F. Taken gr. x. quinine this morning; ordered more at once. At 11 A.M. she had another chill. At 2 P.M. her pulse was 120, and temperature 106° F. I had her put in a bath at temperature of 105° F., which was gradually reduced to 99½° F. Left her in the bath half an hour, when her temperature was found to have fallen to 103° F. Put her back into bed, and rolled her up in a pack. At 4 P.M. found temperature 105° F., and the patient subjectively easy. While in the pack, the pain in the back and headache which she had been suffering from, passed off. At 7 P.M. her pulse was 116, temperature still 105° F. I ordered quinine, gr. v., every three hours.

October 26th, 8.30 A.M.—Pulse, 100; temperature, 103½° F.; has taken gr. xxv. quinine since last night. I ordered gr. xv. more. 1.30 P.M.: Pulse, 100; temperature, 105° F. Syringed the womb and removed a larger amount than at any time before of grumous fluid.

October 27th, 9 A.M.—Has taken gr. xx. quinine since 4 A.M. Head is confused, but is otherwise feeling better. Pulse, 92; temperature, 101½° F. Syringed uterine cavity; removed some yellowish fluid.

From October 27th to November 14th the patient's temperature fluctuated between normal and 100.5° F., and the treatment consisted in the use of quinine, syringing the uterine cavity, which removed grayish mucus, muco-pus, some shreds of membrane, and reddish fluid in greater or less quantities, and the administration of anodynes, stimulants, and tonics, according to indications.

On November 15th the patient's pulse and temperature were normal, and on the 19th she was discharged, as she was up and about and feeling well.

The noticeable facts in the case are: The occurrence of an abortion after the fourth month, with expulsion of the fœtus and retention of the membranes, which were left *in situ;* the occurrence of a febrile temperature of 103¼° F. on the morning of the following day, which abated to 102° in the evening of the same day, with decrease of temperature to natural on the morning of the fourth day; no fever on the fourth, fifth, sixth, and seventh days; a chill on the ninth day, with an evening temperature of 106° F.; the resolution, and, thereafter, the partial control of this fever to the afternoon of the eleventh day, when she had a second chill, followed by a second rise of temperature, reaching 106° F., later in the evening of 106½°; the reduction of this temperature by intra-uterine syringing, performed twice that afternoon and evening, with disinfecting solutions, by substantial doses of quinine, cathartic action, and, possibly, somewhat by natural remittent action; and its control until the morning of the thirteenth day, when she had another chill, and an evening temperature of 106° F., which was temporarily reduced to 103° by placing her in a bath of a temperature of 105°, reduced to 99½° by additions of cold water, in which she was left half an hour—then she was taken out and packed—later in the evening the temperature again rose to 105° F.; a febrile temperature of 103½° to 105° F. during the fourteenth day; the continuation thereafter of a febrile temperature, ranging from 104° F. downward for twenty-three days—making about thirty days in all of fever—and its gradual reduction and final stoppage in that time, by frequent, daily or oftener, intra-uterine syringing with disinfecting water.

Comments.—This case illustrates: (1) That septicæmic puerperal fever may occur from absorption of retained decomposing membranes from a uterine cavity where no abrasions have occurred, and hence that traumatism in the course of the genital tract, as a result of labor, is not essential to its occurrence. (2) That assured prevention of this form of puerperal fever requires that all placental membranes be removed after the expulsion of the fœtus; that is, while fever may not be caused by their retention, as general experience proves, yet an assurance that it will not while they are allowed to be retained is not valid. (3) That the only reliable element of treatment of a puerperal fever, resulting from septicæmia due to absorption of retained membranes, is an efficient and continued syringing of the uterine cavity with an antiseptic fluid until all membranes are washed out. And, lastly, it demonstrates, by the many times the operation was done, without resulting harm, that the introduction of a stream of water into a womb undergoing involution is not as hazardous—as likely to pass through the Fallopian tubes and cause peritonitis—as it has generally been held to be.

THE TEETH IN CONGENITAL SYPHILIS.—At a late meeting of the London Harveian Society, Dr. J. Hutchinson, Jr., spoke on this topic. The fallacy of looking for characteristic signs in the temporary teeth was dwelt upon, their liability to premature necrosis and falling out being illustrated by specimens. Those teeth which in after-life showed syphilitic deformity in the greatest degree were those which calcified first, and which during the year lay the nearest to the gum surface, namely, the permanent incisors and first molars. The three small projections at the cutting edge of the central incisors seen in normal teeth were noticed, and the wearing away or non-development of the median one was described in connection with the formation of the semilunar notch and the narrowed cutting edge. The horizontal erosion of enamel, resulting from mercurial stomatitis in infancy, and its occasional coincidence with true syphilitic malformation of the teeth were illustrated, and stress laid on the fact that the upper central incisors were the real test teeth of inherited syphilis, though many children with the inherited disease presented perfectly normal teeth. No explanation could at present be given for the preponderance of female over male patients observed in connection with inherited syphilitic disease of the eyes and auditory system. Dr. Hughlings Jackson believed that a wide and exact knowledge in the profession of the particular and decisive signs of inherited syphilis mentioned would, by leading to early and definite treatment, save many people from terrible calamities.]

Clinical Department.

AN OBSCURE CASE.

By JOHN J. MORRISSEY, M.D.,

HARTFORD, CONN.

The patient, a young man, about twenty years of age, employed as private secretary to the manager of an insurance company, complained, on arriving home from the office, about 5 P.M., of having suffered during the day from a succession of chills, none of them being sufficient to compel him, however, to desist from his employment before the day's business was finished. He ate quite heartily at supper, but retired early—about eight o'clock. Shortly afterward he began to vomit mixed green and yellowish-looking stuff, but as he had at odd times suffered from so-called "bilious attacks," nothing was thought of the matter, and he assured his mother that he would be all right in the morning. Occasionally during the night there was a recurrence of the vomiting, with consequent uneasiness over the abdominal region. Toward morning this increased, until his brother, who had been attending a ball, arrived home about 4 A.M., and on reaching my house, about half an hour afterward, gave me the particulars of the case as related above. He did not deem the patient in any danger, and as I had seen him in one or two "bilious attacks" before, he (the brother) thought that if I prescribed for the patient, and saw him later on in the morning, it would be sufficient. I accordingly did so, and, some four hours later, on calling at the house, found the patient, to use his own expression, "about one hundred per cent. better." There was still a generally diffused soreness over the abdomen, without being at all markedly localized in any one spot; there was no headache, no backache, no diarrhœa. On the contrary, he had not been to stool for the preceding two days, though the last movement of the bowels had been a large one. His pulse was about 90; the temperature I did not take, as he expressed himself feeling so much better that I did not deem it necessary. The stomach was still somewhat sensitive to the administration of food, so, with a parting injunction to continue the medicine, I left him. This was on Thursday morning, and I did not see him again until about ten on Friday morning. I immediately detected a change in his condition, and when I took his temperature (103.2°) and pulse (130), they confirmed my suspicions, yet, outside of this increase, there was no apparent change. He passed his urine freely, there was no œdema, and nothing indicative of kidney disease. There was still no headache, no backache, no confirmed soreness in any particular portion of the abdomen, but the general uneasiness to which attention has been drawn remained, and was increased by deep pressure. On careful examination of the heart I detected a soft, blowing murmur with the first sound. This, however, I regarded as functional rather than organic. After prescribing tr. digitalis, and arom. spts. ammon. and quinine, I left him, promising to call next day. On the evening of the day (Friday) upon which I had noticed the symptoms mentioned, about 6.30, I was hurriedly called. I immediately went to the house, and found that a great change had taken place in the patient's condition. He was in a semi-unconscious state, from which he could be, however, easily aroused. He spoke rationally when so awakened, but did not maintain his consciousness for any length of time. A profuse perspiration covered his face and hands; there was some photophobia, but not at all marked; and on being questioned concerning how he felt, he said, "Very well indeed," and constantly reiterated the expression. His pulse was 145; temperature not taken. He lay quietly, evidently paying no heed to what was going on about him, except at occasional intervals, when he would rouse himself sufficiently to take part in the conversation, and immediately relapse into his former state. His nose appeared sharpened, a slight bluish ring surrounded the mouth, yet the breathing was not at all labored or suffocative in character. I sent for Drs. Jarvis and Mayer; the former responded, and we gave the patient a hypodermic of about one-sixth grain of morphine. At the doctor's suggestion I drew the urine, and found about two tablespoonfuls, which, I regret to say, was not saved for further investigation, but immediately emptied by the patient's mother, who did not understand what important information it might have given. Just above the heart, on the left side, we found a few râles, but they were mostly confined to an area of about the size of a silver dollar; otherwise his lungs were clear.

The tremendous strain on the heart was a very characteristic factor, but from what cause produced neither Dr. Jarvis nor myself is prepared to say. About two hours after giving the morphine, I gave one-sixtieth grain sulph. strych. It did not appear to exercise any perceptible influence. Brandy had been given in two-teaspoonful doses every two hours, but as I feared overstimulation and consequent exhaustion, considering the patient's condition, I gradually lessened the amount and increased the intervals. Dr. Mayer arrived about 10.30, and by his advice the digitalis and ammonia were given more frequently. No other change was made. The patient lingered until 4 A.M., and passed quietly away. On carefully reviewing the facts, it would seem as if the patient's system had been overwhelmed by some insidious poison, typhoid or otherwise, and was not able to endure the strain, and so succumbed. The facts do not point to pulmonary embolism, but no definite diagnosis was made. No post-mortem was held. I should have stated that even to the last hour the patient continued in his semi-unconscious condition, from which, as when I saw him earlier in the evening, he could be aroused.

PAROXYSMAL TACHYCARDIA.[1]

By FRANK C. BRESSLER, M.D.,

BALTIMORE, MD.

Tachycardia is a trouble of such exceeding interest to the physician that every case occurring is worthy of being reported, and especially those which are not functional only, but associated with some distinct organic heart-lesion.

By tachycardia is meant that condition of the heart in which the heart's beats are increased in number, retaining a perfect regularity in each beat. The number of heart-beats may vary from one hundred to two hundred, or more, per minute. The period of this increased frequency of the heart may vary as to duration, lasting from a few hours to days and weeks. This condition must not be mistaken for palpitation of the heart, since palpitation is (1) induced usually by excitement, stimulants, etc.; (2) the attack is of brief duration; (3) there is absence of severe depression; and (4) there is intermittency of the heart's action.

In order to make the subject of tachycardia plainer, I beg leave to introduce the following history of a case which I have had under observation during the last twelve months:

About one year ago I was hastily summoned, one evening, about eight o'clock, to see an elderly gentleman, sixty-five years of age, about five feet six inches in height, weighing, perhaps, between one hundred and forty-five and one hundred and fifty pounds. I found him sitting in a chair, face pale, pupils moderately dilated, body covered by a profuse sweat, whole body trembling so as to suggest senile tremors, which, however, ceased on patient walking about; breathing rapid, like that seen in a person who has run rapidly for some distance, pulse so rapid as not to be counted. The temperature was not taken, as it was forgotten. The symptoms were of such a nature as to make me think of angina pectoris, or internal hemorrhage, but the attack, after lasting about two and a half hours, ceased entirely, and my patient's condition was as good as before, except a slight malaise. From the absence of pain about the præcordia, and because of the perfect and rapid recovery, both of these troubles were excluded, and a diagnosis of palpitation of the heart was made. As to the cause of this attack, none could be assigned, the patient saying "that it came upon him suddenly while sitting in the store, and that nothing had either excited or worried him to cause any nervous disturbance." He was a moderate smoker—not of cigars, but of a pipe—smoking, perhaps, four or five pipes in a day, which he had always done from youth up. The case finally passed out of my memory, when one Saturday evening, about three weeks ago, I was again sent for, and found my patient in precisely the same condition I had seen him in at my last visit. I gave him some tincture of digitalis and belladonna, but with little immediate effect. This attack lasted nearly three hours. After the attack was over, the following day I made a close examination, in order to find the cause, but all questioning elicited nothing satisfactory. From these two attacks I had seen him in, and from two others which were not so severe during the interval, I came to the conclusion that this was not a case of palpitation, but one of tachycardia, paroxysmal in nature. The most interesting part of the whole thing was that it was associated with an organic lesion, viz., mitral regurgitation.

---

[1] A paper read before the Medical and Surgical Society of Baltimore, December 8, 1887.

Authors generally state that tachycardia is a functional condition, and only in rare cases associated with organic lesions. Flint, in the last edition of his work on the practice of medicine, states that he had met with but one instance of this condition, but it was not associated with any heart-lesion. I also found an article (published in THE MEDICAL RECORD, April 30, 1887) by Nothnagel, on paroxysmal tachycardia, in which he related a case in a young man, thirty years of age. During this lecture he made the statement that paroxysmal tachycardia in cases of organic heart disease was very rare, and that he did not remember a similar case in medical literature.

My patient dates his trouble to exposure, having been out on a raw, chilly night some seven years ago. Previous to this time he never had had any trouble with his heart, not so much as palpitation. He has about three or four attacks a year, which come upon him very suddenly, independent of any exciting cause: suddenly he notices his heart beginning to beat rapidly, then all the above-mentioned symptoms follow. Up to the present time his longest attack lasted four hours. So far as exciting cause is concerned, he can assign none—each attack has come upon him while engaged in such pursuits as do not generally give rise to palpitation. In his last attack he stated he was standing on the sidewalk, leaning against a box; had not spoken to anyone for at least fifteen or twenty minutes, and his mind was free from worry or thought; and, in fact, he stood outside "to kill time," showing that there was no exciting cause to induce this condition.

During the intervals of the attacks the pulse is regular and moderately full, varying from 72 to 84. Health otherwise is good, digestion perfect; sees that his bowels are regularly moved, and avoids all those things which might be injurious to him.

As to the pathology of this condition, so far from the rarity of the trouble, it is simply a matter of conjecture, as I do not think a post-mortem has been made on any of the afflicted patients. Still, with our knowledge of the nervous mechanism of the heart, we must know that it depends upon some perverted condition of the nervous arrangement; whether it is central or peripheral we cannot say. I look upon the trouble as one in which the centre which presides over the cardiac movements is temporarily inhibited; but whether this is induced by some vascular change taking place suddenly in this centre, owing to some peripheral cause, or to some disturbance at some distant part in the brain (perhaps temporarily, likewise), which fails to transmit the impulse to the centre, thus failing to stimulate it, in consequence of which the inhibitory action of the heart is interfered with, resulting in increased heart's action, I am not able to prove. But with all that, I think the trouble is situated in or near the cardiac centre—at least in that portion of the medulla wherein the centres for sweating, respiration, and cardiac movements are located, since in Nothnagel's case deep inspiration moderated the cardiac movements considerably, while other experiments had no effect on it.

SULPHIDE OF CALCIUM IN PULMONARY PHTHISIS.

By C. B. WITHERLE, M.D.,

ST. PAUL, MINN.

I WOULD like, through the columns of THE MEDICAL RECORD, to call the attention of the profession to the use of sulphide of calcium in pulmonary phthisis. My experience, though not extensive, leads me to think it of value. I have noticed improvement in nearly every case. In advanced cases this improvement has been only temporary. In two cases of commencing phthisis (one of three, one of six months' duration) there has been an entire cessation of morbid symptoms. I have also found the drug effective in several cases of obstinate cough, in which no pulmonary lesion was determined.

I begin with one-half grain in pill every two hours, increasing the dose until disagreeable symptoms (usually eructations of gas) are produced. One grain every two hours is the usual amount that can finally be taken without discomfort.

There is good evidence that sulphuretted hydrogen, or some compound of it, is absorbed into the blood when sulphide of calcium is administered, and this method has none of the disadvantages or dangers of the Bergeon treatment. I hold no theory as to the action of sulphuretted hydrogen upon the bacillus tuberculosis. If it has such action, it appears probable that it is by interfering with some nutritive condition of the bacillus peculiar to its existence within the body-tissues, and not as a direct germicide.

The idea of using sulphide of calcium was naturally suggested to me by the Bergeon treatment, and by the established use of the sulphides in certain suppurative diseases. No doubt the same idea has occurred to others. I have, however, seen no suggestion of the method of treatment that I have used, and therefore deem it worth while to lay my results, limited as they are, before the medical public. We should all be ready to catch at straws in the treatment of phthisis, and I hope that others, with greater opportunities than I have, may be induced to try the treatment that I have indicated, so that my results may be confirmed, or shown to be coincidences rather than results. I wish to emphasize the point that it is only in commencing cases of phthisis that I anticipate any marked benefit.

PERITYPHLITIC ABSCESS OF THE PERITONEUM — INCISION AND DRAINAGE — RECOVERY.

By ARTHUR A. GILLETTE, M.D.,

WESTERNVILLE, N. Y.

ON November 15, 1887, Mr. V——, aged forty-three, while engaged in chopping wood, was suddenly seized with severe abdominal pain. With the exception of some slight abdominal uneasiness for a few days previous, to which he had paid but little attention, he had been in good general health.

Physical examination two or three hours later revealed general abdominal distention, with marked tympanitic resonance, and moderate tenderness on percussion. Morphine was given freely for a few days, and the patient said he was feeling better, until the sixth day, when he said the pain had all settled in his right side. On making an examination a hardened area, two inches square, and with well-defined margins, was found just above the anterior superior spine of the ileum. It was very tender, and percussion over and around this spot gave tympanitic esonance.

The patient's condition remained about the same until the fourteenth day of the attack, when the tenderness over this area became so extreme that every movement elicited a groan, and no satisfactory examination could be made. On the evening of this day his temperature was 102° F., and pulse 100. Suspecting the formation of deep-seated pus, and having obtained Mr. V——'s consent to an operation, Dr. T. M. Flandrau, of Rome, N. Y., was sent for, and saw the patient, with me, on the morning of November 30th. Chloroform was given, but on careful examination no fluctuation could be detected. A large-sized aspirator-trochar and cannula was then plunged into the centre of the hardened spot, one inch and a quarter above the anterior superior spine of the ileum, and after some searching, about three ounces of bloody pus, having a distinct fecal odor, together with a small quantity of intestinal gas, was obtained at a depth of four inches, the cannula being directed backward and slightly inward, toward the median line. A free incision one inch and a quarter above and parallel to the crest of the ileum was then made across the tumor, and the muscles were carefully divided until the thickened peritoneum was reached; then, with the cannula (which had not been removed) as a guide, the knife was plunged into the abscess-cavity. After the escape of a quantity of foul matter, too thick to flow through the cannula, the finger was introduced, and the thickened walls of a peritoneal abscess thoroughly examined, but nothing further was found. A drainage tube was then introduced to the bottom of the cavity, and the external wound closed. The after-treatment consisted in the thorough irrigation of the abscess-cavity daily with carbolized water, until the discharge entirely ceased. The tube was withdrawn on the tenth day, and the patient has made an uninterrupted recovery, and is now in perfect health, entirely free from pain and tenderness. The wound is healed, and at the time of writing the patient is able to walk a mile in the open air.

Within an hour after the operation Mr. V——'s temperature dropped from 102° F. to 98½° F., and pulse from 100 to 60, and there has been no rise in either pulse or temperature since.

THE INTRA-NASAL PLUG.

By J. M. W. KITCHEN, M.D.,

NEW YORK.

Surgical literature has so little to say in relation to the intra-nasal plug that I judge its uses are not generally known or appreciated. This instrument has such an important place in my own practice, and fulfils so many useful purposes, that I think its virtues worthy of being brought to general notice. I use the intra-nasal plug for the following purposes: *First*, To control hemorrhage and oozing; *second*, to prevent the adhesion of opposing surfaces after intra-nasal operations; *third*, to repress too abundant tissue-formation during repair; *fourth*, as a splint; *fifth*, to gain increased space by dilatation, either without operation or in conjunction with the various drilling, cautery, and other operations; *sixth*, to apply continued medication. Several years ago I devised, and have used continually since, what I consider the *ne plus ultra* of intra-nasal plugs. It consists of a core of thin sheet-tin, cut with a stout pair of shears to the size and shape required—the requirements differing with each case. This is wound with absorbent cotton to the desired thickness—usually being padded in particular parts. This gives a plug of sufficient stiffness to be inserted into almost any part of the nasal cavities, and yet is sufficiently flexible, elastic, and thin to allow of its easy introduction. Before being placed *in situ*, the cotton is saturated with any desired medicament, is lubricated with vaseline, and is then introduced with the aid of dressing forceps. It may be allowed to remain in position two or three days if antiseptically prepared before introduction, and if the patient snuffs up cleansing solutions several times each day. This plug is usually well borne, though somewhat annoying to patients the first two days. Following the methods recommended by Mackenzie, Wagner, and others, I was never able to accomplish by intranasal dilatation any results at all satisfactory, but by the use of this plug quite remarkable results can be quickly secured. Care should be taken not to allow the patient to go beyond ready access if the plug is inserted so as to exert any great degree of pressure, as the discomfort may become intolerable. Also, pressure so great as to produce sloughing must be avoided. The aim should be to exert mild but continued pressure. By bending and shaping the tin core to suit, pressure can be made at any particular point. The ordinary plug is difficult to introduce, to adjust accurately, and to keep in place. It is also usually not well borne. The plug I have described has none of these disadvantages, nor any other of which I am aware. There are very few intra-nasal operations that I would care to undertake without the after-help of this useful addition to my armamentarium.

168 West Fifty-eighth Street.

DETACHMENT OF THE PLACENTA AND ALARMING HEMORRHAGE BEFORE THE BIRTH OF THE CHILD.

Dr. G. W. Squires, of East Avon, N. Y., reports the following: "I was called, December 10, 1887, at 8 A.M., to attend Cora W——, aged sixteen, unmarried, who had been in labor all the night before. I found the os well dilated, and the parts relaxed; vertex-presentation; pains every five minutes, without any advance. After waiting a while and seeing no improvement in the case, I made pressure with the hands over the uterus during pains. As no benefit followed this, I gave two small doses of fluid extract of viscum album. Another pain coming on, the nurse was directed to press on the uterus while I made an examination. The woman commenced to flow. I could feel the hot blood gush past the head at every pain. I was satisfied immediately that the placenta had been detached by outward pressure. I had my forceps in readiness, applied them as quickly as possible, and delivered the child, a nine-and-one-half-pound boy. The placenta was loose in the uterus, and was easily removed by hooking it out of the cervix and vagina with the finger. The child was floating in blood, which came with a gush at the time of delivery, but was dammed back by the placenta in the cervix. By manipulation, pressure, ergot, etc., the uterus was brought to contract and the hemorrhage was controlled. Is it a common occurrence for alarming hemorrhage to occur before the birth of the child, except from placenta prævia? and is it a safe practice to bring much pressure to bear on the uterus during labor?"

SWALLOWING PENNIES.

Dr. S. Tynberg, of this city, writes: "Having lately read of several cases where foreign bodies were swallowed by children without, as a rule, any serious consequences, I desire to contribute the facts of a case which in some instances are unique. On the 9th inst. Mr. M—— called at my office for the purpose of ascertaining whether any serious symptoms could occur from the fact of his child, a girl three years of age, having swallowed one or two copper pennies—he was not certain how many. He informed me of his intention of giving the child an emetic at the time of occurrence, but was induced by his wife to wait until the arrival of medical aid. As the child was in good spirits after the accident, and complained of no bad after-effects, I soothed the anxious parent and gave directions for the treatment of the child. I merely ordered a diet the principal constituents of which should be oatmeal-gruel and milk, hominy, rye-bread, a few figs or dates, and some stewed prunes. The child had a slight evacuation of the bowels the next morning, but the coins did not appear. I visited the child in the evening, and was about to order a cathartic, when the patient had a voluntary movement, passing the coins (two) without any pain or inconvenience. On examining these, I saw two new 'copper pennies,' closely adhering to each other, in which condition they were probably swallowed, and which relative position they maintained during the entire digestive process and circuit through the alimentary tract, the duration of the latter being about twenty-two hours. The exposed surfaces and part of the edges were covered with verdigris, while the two adjacent surfaces were untarnished, and presented the appearance of a coin recently from the mint. It is this latter fact which justifies the assumption that both pennies were swallowed simultaneously. The child was well, and is so to date."

INSUFFLATIONS OF QUININE IN WHOOPING COUGH.

Dr. W. P. Swett, of Terryville, Conn., writes: "In your remarks regarding the treatment of pertussis, the insufflation of boracic acid as used by Dr. Holloway is mentioned. I wish to call attention to the treatment by quinine insufflation as detailed by Professor Forcheimer in the January number of the *American Journal of Obstetrics* for 1882. I have in mind thirty cases, all under ten years of age, in which there was a positive and immediate change for the better after the morning and evening insufflations of the first day, the invariable result being fewer paroxysms both by day and night, better sleep and appetite, and in all the solitary cases retention of food from the first. The separation of the patients far beyond hearing distance would, in reason, very materially assist in any plan of treatment. Sulphur-fumigation was a decided help in the families in which there were two or three cases. The adults, in these families, who had a sympathetic cough all remarked the relief they themselves felt, together with the children. That better results are obtainable when the insufflations are continuously performed by the physician is true, but an ordinarily intelligent person can, and in the country must, do it, with, of course, or by the direction of the doctor—and the reports of the case, if carefully kept, will more than satisfy all concerned."

SOME TOXIC EFFECTS OF ANTIPYRINE.

Dr. C. F. Barber, of Brooklyn, writes: "The following case came under my notice but a few days since, and as illustrative of the poisonous effects of our new antifebrifuge, antipyrine, I place it before the readers of The Medical Record. The patient, a man of robust constitution, feeling slightly indisposed, took, on December 11th, a dose of compound cathartic pills. These acted with their usual promptitude, and so relieved him of his bad feelings that he attended to business on the following day. Returning home, however, about supper-time he again experienced a slight indisposition with a mild headache as the prominent symptom. He had eaten but little during the day, and that, with the effects of four compound cathartic pills, probably accounted for his ill feelings. However, having some antipyrine in the house, and having heard that it acted well in headache, he took fifteen grains, with the following result: Retired at once. Was no sooner in bed than intense itching began to annoy him, commencing on the face and extending over the whole body. Immediately following this pruritus an erythematous blush covered the body. This, in a short time, resolved itself into the characteristic lesion of urticaria. The face was so markedly swollen that the patient's features were entirely obliterated. The urgent symptoms disappeared quickly after the administration of an emetic, and after mild purgation the patient was again restored to his usual health."

A CASE OF OVARIOTOMY.

Dr. Gustavus Zulch, of New Knoxville, O., reports the following case: "Mrs. K——, forty-two years of age, the mother of eight children, had been a healthy woman up to July last, when she was taken with a diarrhœa, and hemorrhage per vaginam, and all summer she suffered from dysentery, uterine hemorrhage, vomiting, and fever. I was not called until about the middle of October, when, on examination, I found a tumor occupying the abdomen similar in extent and shape to a womb in the eighth month of pregnancy. A careful examination gave ample proof that it was pathological. My hopes that an improvement in the patient's general condition would give us a fair chance for a successful operation were not realized; I concluded to operate, nevertheless, seeing that a fatal issue would otherwise soon take place, and did so on November 19th, with the fullest consent of my patient, her temperature at the time of the operation being 102°; pulse, 120; respiration, 45. The abdominal cavity having been opened with antiseptic precautions, we found, as we had expected, a tumor, adherent to abdominal walls and intestines, but a moderate force of the hand would suffice to sever its attachments. On tapping it with Thomas' trocar a bloody fluid of a cadaverous smell, and soon becoming so thick that it blocked up the cannula altogether, was found to be its contents. The size of the tumor having been diminished but little by the tapping, I extended the abdominal incision to a sufficient extent to enable me to get it out entire. The short, fleshy pedicle was ligated, and dropped into the abdominal cavity. The wound was now closed by a double suture. The peritoneum was sewed separately with fine silk and by a continuous suture, the rest of the wound was united by a deep silver wire, and a superficial silk suture. A heavy antiseptic dressing was retained by a many-tailed bandage. The tumor, weighing fifteen pounds with its contents, consisted of one large cyst, the inner wall of which looked like a half-rotten placenta, and a few small cysts containing a colorless fluid. The patient lived forty-two hours after the operation. She suffered no pain, but her temperature was never quite up to normal; she was covered by a cold, clammy sweat, and pulse and respiration went up steadily until she died. A post-mortem showed wound and contents of abdominal cavity to be in an excellent condition. No peritonitis, no hemorrhage."

The Effect of Opium on the Higher Animals.—It has recently been observed that opium affects apes just as it does men, producing all of the physical symptoms, and strongly suggesting the presence of some, at least, of the typical psychical accompaniments. A certain ape would always follow any opium-smoker, would look for the remnants which the smoker left unused, would cry when not admitted to the room where smoking was going on, and so on. The habit takes the same possession of them that it does of men. Apes who are in the habit of getting a little opium are inactive, dull, and useless if they miss their usual dose; and a Chinese merchant is recorded as having a large ape who howls piteously when his usual ration of the drug is denied him. Similar effects have been observed in dogs, and strikingly illustrate the functional similarity of the central nervous system of the higher mammalia.—*Science.*

Progress of Medical Science.

Uterine Diseases and Insanity.—Dr. Alice M. Farnham, in *The Alienist and Neurologist*, combats the wide-spread notion that uterine disease is largely responsible for insanity. From a study of this topic she has been led to the following conclusions: While the female reproductive organs and the brain are closely associated, often acting and reacting upon each other, uterine disease alone is seldom or never the cause of mental alienation—other conditions, as hereditary predisposition to insanity, poor bodily health, or mental worries, one or all furnishing the necessary adjunct to the development of disorders of the mind. In insane women irritation of the genitalia often gives a peculiar character to the mental condition. Menstruation, like any periodic lowering of the standard of general health, frequently acts, in cases of mania, as the excitant of the most marked maniacal outbursts.

Excavating Myelitis.—Drs. Joffroy and Orchard recently read a paper before the Academy of Sciences on excavating myelitis. This morbid condition is also known under the designation of hydro-myelia, syringomyelitis, and peri-ependymal myelitis. In two cases they found evidence of a slow inflammation, and they consequently reject the view that the cavities result from enlargement of the central canal from cystic degeneration of a hemorrhagic or gliomatous focus. They believe that the distribution of the vessels to the centre of the cord explains the anatomical disposition of the cavities. According to them, the course of events is first a myelitis affecting a special site in the neighborhood of the ependyma. This inflammation causes an obstruction of the vessels supplying the gray matter around the ependyma, and consequently there results a softening which leads to excavation. The formation of a limiting wall to the cavity follows, and its pathogeny is therefore the same as that of the wall of ancient foci of cerebral hemorrhage or softening.—*La France Médicale.*

Methylal.—At a meeting of the London Medical Society, Dr. Richardson read some notes on methylal, of which the following is a summary (*The Lancet*): 1. Methylal is hypnotic and antispasmodic. 2. Its action lies between methylic alcohol and ethylic ether; it may be looked on as a volatile alcohol, and resembles closely pure methylic alcohol in action. 3. It can be administered by inhalation as vapor, by hypodermic injection, and by the mouth in aqueous solution. 4. It reduces arterial tension, and by local action excites glandular activity. 5. The sleep it produces is not profound unless the dose be excessive; it is quickly eliminated, and leaves no serious effects; it causes no vomiting or stomachic disturbance. 6. A fatal dose by inhalation kills by complete relaxation of the muscular fibres of the heart, leaving the heart distended with blood and the vascular organs intensely congested. 7. It combines with ether, alcohol, amyl nitrite, and many other remedial agents with which it acts in concert, and equalizes their action by reason of its own solubility. 8. Its tendency is to maintain the fluidity of the blood, and it may therefore be of service in combination with ammonia. 9. It promises to yield a safe and effective anæsthetic mixture in combination with ether. 10. It reduces the animal temperature, but not to the same degree as common alcohol. 11. Used as an anodyne, it passes out of the body without producing organic injury, when not often repeated. 12. But, like all bodies of its class, it must be given in increasing quantities in order to keep up its effects, and it would soon yield evil as well as good by its habitual use in the community at large.

Colchicum for Gout.—Dr. Carter believes that colchicum should be avoided in all cases of gout attended with debility and cardiac feebleness, and that its use should be limited to early attacks of a sthenic type, and when the pulse is one of high tension. From the liability of colchicum to depress the system and to interfere with renal elimination, its administration should not be continued for a longer period than is absolutely necessary for the relief of pain. In order to prevent the employment of a larger quantity than is necessary for this purpose, it is desirable to give the drug in moderate doses, repeated at short intervals, rather than in a large single dose. There is no evidence of the curative influence of colchicum and, in spite of the relief afforded, it tends to favor recurrence, and it is safer to avoid its use altogether if possible. Dr. Carter has found that such dilators of arterioles as nitrite of amyl, nitro-glycerine, and nitrite of sodium are scarcely inferior to colchicum in affording relief to gouty inflammations. Veratria, a powerful vascular depressant, is the principal constituent in a well-known nostrum for gout (Laville's). Besides filling the cutaneous arterioles and swelling the skin, which actively perspires, with lowering of the general blood-pressure, colchicum diminishes the function of the sensory nerves, and may in this way tend to relieve pain. The sweating may also aid elimination, and relieve the kidneys from some of their work.—*Birmingham Medical Review.*

The Significance of Axillary Adenitis.—It is believed by M. Grancher that tubercular diseases of the lungs may through the mediation of the pleura infect the ganglia of the axilla (*The Lancet*). This peculiarity does not appear hitherto to have attracted much attention, and it is thought that the occurrence of such axillary adenitis may not be rare. The knowledge of these facts is regarded as having much importance, not only from a doctrinal point of view, but also from the stand-point of diagnosis. Grancher advises that henceforth every case of phthisis should be examined for axillary swellings, and, conversely, that every case of axillary adenitis should be examined for the signs of pulmonary mischief.

Benzol in Pertussis.—A correspondent of the *British Medical Journal* writes that for many years he has used benzol, and it alone, internally for this complaint. In spite of its being dispensed by many different chemists, he found great uniformity in the medicine supplied. He has great confidence in the "benzol puriss." supplied by chemists for many years past. The spasmodic cough yields, expectoration diminishes in quantity and viscidity, and is more readily brought up, while the sickness so frequently terminating an attack of cough soon disappears. The taste is certainly pungent, and at first disliked, but, after a short time, children seem to acquire a taste, and even ask for it. He has treated at least one hundred cases with it alone, nothing else internally (except added to moderate the flavor), with stimulating liniments over the thorax and nose. Since he first commenced its use he has lost only one case of whooping-cough, and this occurred in an infant, and was accompanied by convulsions: the child was aged twenty-four days at death. He gave it with mucilage and tinct. chloroform. co. in from two to ten minim doses.

Fatal Stricture of the Bile-duct without Gall-Stones.—At a meeting of the London Clinical Society (*The British Medical Journal*), Dr. Sidney Phillips reported the case of a man, aged sixty, who came under his care at St. Mary's Hospital with obstructive jaundice without obvious cause. The patient had had gout, but never syphilis, and for some years had been a very hard spirit-drinker. He had never had colic, vomiting, or any symptom of the passage or impaction of gall-stones. There was no evidence of perihepatitis. While under treatment the gall-bladder became gradually more and more distended, and the jaundice more intense. Much cutaneous irritation, with xanthelasma and purpuric blotches on the skin, was set up, and the patient, after five months, died of exhaustion. At the necropsy there was found a stricture of the common hepatic duct, much resembling a "cartilaginous" stricture of the urethra. There was no ulceration or adhesion of the mucous surface, but the stricture resulted from a tough fibrotic contraction of the outer wall of the duct. The gall-bladder was full of clear fluid. The liver was simply enlarged from the obstruction of the duct. Dr. Phillips pointed out that this case, though rare, together with three somewhat similar cases recorded by Dr. Moxon, Dr. George Johnson, and Mr. T. Holmes, contributed to establish the fact that stricture of the bile-duct might exist without any symptoms of gall-stones. This was important in the diagnosis of the cause of obstructive jaundice, and might also be of service in the treatment; for, seeing the successful results of cholecystotomy, etc., it might be possible to give an exit to the obstructed fluid, or at any rate to postpone one danger, that of rupture of the gall-bladder. Dr. Phillips submitted also that it was very probable not only that stricture was set up without symptoms of gall-stones, but also that it might arise from causes entirely unconnected with them. In favor of this, stricture sometimes occurred above the cystic duct, and in a position, therefore, where gall-stones would not pass. The absence of symptoms of gall-stones was also a presumption against their having been present, but the main point which seems to prove that the stricture was not always due to calculi was that in some cases, as in the one he had recorded, the mucous membrane was not abraded, and the stricture was formed by contraction of the outer fibrous coat of the duct. Sufficient cases had not been reported to decide what causes, if not gall-stones, would produce stricture, but possibly long catarrh might lead to stricture of the bile duct as gleet led to stricture of the urethra

Dogs in Relation to Hydatic Tumors.—Dr. Ollivier, in a communication on the subject of the relation between the *tænia echinococcus* of dogs and hydatid cysts in man, observes: "The number of hydatic cysts in a country is in direct proportion to the number of dogs." Facts seem to confirm this theory, for they show that there are more hydatid cysts in hill-districts than in the lowlands, in the country than in towns. The author cites several cases observed by him, in which the cyst was plainly traceable to previous intercourse with dogs, in patients fond of these animals. A long period, sometimes years, may elapse before the echinococcus develops itself, but the cause is none the less evident. Children are always fond of dogs, and like to play with them, and these pets are affectionate and caressing, and have a bad habit of licking; in this way the animal's tongue may prove a ready means of propagation of the eggs of tænia. It is also possible that they may be inhaled when, in very dry weather, these eggs are carried about by the wind. This would explain certain cysts in the respiratory organs. The penetration into the human organism, however, generally takes place through the digestive organs, by means of salads, green vegetables, fruit, and other aliments imperfectly cleaned; or by water from ponds, reservoirs, or wells contaminated by dogs resorting there to drink. The author points out the precautions which should be taken to diminish the danger of propagation of this parasite: greater care in the choice and cleanliness in the preparation of certain articles of food; avoidance of unfiltered water, and particularly of stagnant water of any kind; and, above all, less intimacy with dogs, particularly in the case of children, who should be carefully watched. He condemns altogether house-dogs of all kinds, as being a source of continual danger as regards the propagation of the eggs of *tænia echinococcus*.—*The British Medical Journal.*

The Treatment of Peritonitis by Laparotomy.—The idea of opening the abdomen and washing out the peritoneal cavity for peritonitis seems to have been suggested as far back as 1848, but the practice, for reasons which it is not difficult to conceive, has progressed but slowly (*The British Medical Journal*, November 12, 1887). It was first proposed for acute peritonitis, and later on it has been employed with marked success in the treatment of encysted and tubercular peritonitis. A discussion took place recently at the London Clinical Society which gives a good idea of what has so far been accomplished in this direction. So far as concerns suppurative peritonitis, the rules apply which apply to suppuration in serous cavities elsewhere, the knee-joint, for example. There is practically no alternative save the "expectant" treatment, which, with the brilliant record of cures before the profession, would be altogether unjustifiable. The only point on which opinions differ is as to the desirability of draining the peritoneal cavity through the abdominal wound. Mr. Barwell was strongly opposed to this, as useless and possibly dangerous, for mechanical reasons, but was evidently partial to the idea of draining through Douglas' pouch in female patients. The latter procedure is viewed with some disfavor by gynecologists in their abdominal operations, and appears to have dangers of its own. The question, therefore, is whether drainage is indispensable, or whether it is not. Mr. Barwell maintains that it is best dispensed with; Mr. Frederick Treves, on the contrary—and he expressed the opinion of most of the speakers—considers drainage an essential step in the operation. Experience alone will show which is right; possibly there are varieties which may require it, and others in which it is less essential. The operation has not yet been performed on a sufficiently large scale to enable definite rules of conduct to be laid down, but common sense would suggest that if drainage of any kind be thought desirable, it should be planned with due regard to the law of gravitation.

Surgeons of the old school cannot fail to be surprised at the ease and safety with which the peritoneum can be cut into, sponged, and irrigated. This is especially the case when the membrane has been the seat of chronic inflammatory changes, as in tuberculosis. The result in many cases would seem to warrant the use of the word "cure" in reference to the tuberculous condition which was proved to exist. Not only did the local tubercular lesions become quiescent, or even disappear (so far as can be judged), but any pulmonary symptoms also underwent marked improvement. In a paper read before the congress of German surgeons, recovery took place in thirty out of thirty-six cases. If the diagnosis of tuberculous peritonitis is to be accepted—and every precaution would appear to have been taken to insure its accuracy—then our views of the pathology of tuberculosis must needs be modified. This, indeed, may underlie the reluctance manifested by many eminent authorities to accept of the natural conclusion to be drawn from the startling results obtained. A more mature experience will enable us to ascertain with greater precision the indications for treatment and their bearing.

The Duality of the Brain.—In a paper read before the Académie des Sciences (*La France Médicale*, October 26, 1887), Brown-Séquard reported the results of some experiments going to show that anæsthesia, paralysis, and local elevation of temperature, caused by an organic lesion of the nervous centres, may be transferred from one to the other side of the body under the influence of a second lesion of these centres. From this he concluded that these manifestations are not necessarily the effects of the destruction of certain nervous elements possessing certain functions, but may be the results of pure dynamic actions exercised at a distance through the irritation caused by the lesion. He further concluded that one half of the brain could serve for sensation, voluntary movements, and vaso-motor actions for both halves of the body, and that the same was true for the spinal cord, at least as far as sensation and vaso-motor action were concerned.

La Lombardia quotes the following illustration of the effects of professional competition: A doctor—we presume one qualified to kill, if not to cure—advertises: "I undertake, whenever my treatment is not followed by cure, to bear half the expenses of the funeral."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 7, 1888.

THE CONDITION OF OUR QUARANTINE.

THE conference committee of the New York Academy of Medicine which was appointed, at the suggestion of Health Commissioner Joseph D. Bryant, to examine and report upon the present condition of our quarantine, has set forth its labors in a lengthy and formidable document of objections and suggestions. The conclusions reached are summed up in a few words, to the effect that the arrangements at quarantine are entirely inadequate for the protection of this city from disease. This is by no means surprising intelligence, and it is a matter for congratulation that the question of care of immigrants has now been fairly brought to the surface of calm discussion. The machinery of the quarantine commission has been so shamefully crippled by outside political influences that the time is opportune for some direct and effective interference on the part of the Legislature and State Executive. We are well aware that there have been many good reasons advanced for the non-effectiveness of quarantine, or rather the impossibility of perfectly carrying out its provisions. There are, it is true, a multitude of considerations bearing upon collateral conditions which have to be taken into account. Even in face of the fact that the good of the many makes it necessary to sacrifice that of the few, there is a limit to the restraint of personal liberty, as well as a latitude to the demands of commercial intercourse. It is, however, not necessary to discuss these points at this time. In the present state of professional and lay opinion, it behooves the government to get all the good it can out of quarantine, and this is still very considerable.

This brings us to the point of saying that there is no excuse to be offered by the authorities for not properly caring for the necessities and comforts of the unfortunate sick ones who are forced to be under their charge. It is more than incumbent upon the custodians of quarantined individuals to do this, as the sufferings of the subjects are entirely under control. The hospitals on Hoffman and Swinburne Islands are not fit for their purposes. Hence, we are not surprised to hear that unless radical changes be made there will be more than the ordinary danger, with the coming of warm weather, of disseminating disease throughout the city and thence throughout the country.

In any attempt at correcting abuses there is nothing like getting down to the facts of the case. The latter has been very effectively done by the committee in question, the members of which are well-known and impartial gentlemen, who have no interests save those of right and truth to subserve. Hence, their statements and suggestions are deserving of every consideration. The defects which are pointed out in the elaborate report are very serious, and we call attention to them in our summary review for the purpose more particularly of enforcing the recommendations of the committee for radical changes in the whole system. We are informed that the ground of Hoffman Island is soft, uneven, and full of recesses in which water and refuse are retained without any chance of being cleaned. The present condition of the buildings used for the residence of quarantined people is so bad that it is recommended that they be razed and remodelled. The supply of water is insufficient, and warm water is almost entirely wanting. For a population now there of more than five hundred persons, there are only about four water-closets, each closet having three or four hoppers, some of which are not flushed at all!

The cleansing and disinfecting plant is entirely inadequate, making it impossible either to cleanse the clothes or the persons of the quarantined, or to keep them clean. The arrangements of the islands are by no means such as allow of perfect isolation of the infected from the suspected. Numerous detailed suggestions are made to meet the necessary requirements, which comprise the reconstruction of the "rip raps," the building of walls of separation on different parts of the island, and of rearranging the compartments of the buildings in case it be considered necessary merely to remodel the latter.

That it should be considered necessary to recommend a proper flushing-tank for the sewers, and that "no sewage should be allowed to pass into the bay without being subjected to chemical treatment," needs no comment upon the necessity for the inspections made. The disinfecting plant, which should be situated near the waters, we are told should consist of suitable apparatus for a superheated dry temperature of 220° F., and for moist steam under 15 or 20 pounds pressure. The materials disinfected should be separated or individualized at one end, and removed from the other by separate people.

It is also recommended that a resident medical officer, who shall also be superintendent, be appointed and have under his control a full corps of competent nurses. The wards should be supplied with a large stock of vessels suitable for receiving and disinfecting the dejecta of patients before they are committed to the sewer.

A new filth-proof morgue should also be constructed, consisting of a room for storing bodies, and another to be used for their disinfection, embalming, and for autopsies. The dead bodies should be subjected to such processes as would render them before burial innocuous, and prepare them for a decay which would not imperil the living.

As we before intimated, it is impossible, and, indeed, unnecessary, to go over in detail the different recommendations as to size and situation of rooms, ventilation of pavilions and cellars, construction of laundries, arrangement for drainage, etc.; suffice it to say that they are in keeping with the advanced sanitary requirements of the day, all urgent and necessary, reasonable and possible.

We doubt not that the voice of the committee will now be heard, that the public will be satisfied that a radical reform of the whole system is called for at once, and that the time for political dickering has passed. His Honor the Mayor, the Board of Health, and the Health Officer of the Port are in perfect accord with the Committee, and nothing now remains but sufficient funds to carry out the plans. The latter can be most economically done by tearing down all the old buildings and building anew—in fact, this is the only sensible way of striking out all the objectionable conditions, and laying a broad and sure foundation of radically effective reform.

REPORT OF THE SURGEON-GENERAL OF THE ARMY.

THE annual report of the Surgeon-General of the Army for 1886–87 contains a somewhat new feature. The records of sickness and mortality among the troops are classified according to their location in different geographical divisions of the country. These divisions are very nearly the same as those used in compiling and arranging the vital statistics of the United States census, and are based upon certain common climatic conditions. The records are made more instructive by the addition of a colored map, showing these different regions. The average strength of the army in the past year was 23,572, and the number of cases of sickness recorded was 29,761, or 1,263 per 1,000. This is lower than the average for the past decade.

The death-rate was 8.8 per 1,000, which is also lower than the average, or 11.4 per cent.

The average duration of sickness was eleven days. This is about the same as that in the Prussian army, and is less than that in the English army. The average death-rate of the United States army on a peace footing is higher than that of the European armies, which range from 4.6 (Prussia) to 10.6 (Italy).

Thirteen per cent. of all the time lost by sickness was due to alcoholism and venereal diseases.

A section of the report is devoted to the hygiene of the army, and it is shown that much attention is now being given to the improvement in the sanitary condition of the quarters occupied by troops, and to such measures as would be likely to ward off sickness in general.

The Army Medical Museum has received 2,123 specimens during the year, making a total of 26,072.

The more interesting specimens added to the museum collection during the year ending June 30, 1887, were a series of plaster casts and bony preparations collected by the late Professor F. H. Hamilton, of New York; models of the heart and vessels of various fishes, mussels, etc., prepared by Auzoux, of Paris; skeletons and crania of ancient Laps and Finns: a series of corroded metal injection specimens of the vessels of the kidney, liver, and lung, and a series of old microscopes illustrating the gradual improvement in these instruments.

There were added to the Medical Library 6,824 books, 3,067 theses, and 9,955 pamphlets. Volume VIII. of the "Index Catalogue" has been issued, and the work on Volume IX. is well advanced.

It will be seen that the report of Surgeon-General Moore contains a number of interesting details, and reflects great credit upon the efficiency of the army medical service.

DEFECTS IN THE TEACHING OF ANATOMY.

THERE are few physicians who, recalling their student days and the slumberous hours of the anatomical lecture, will not admit that the methods of teaching this branch in many colleges are fundamentally wrong.

The impression still left on many from their student experience is, that lectures are somewhat superfluous academic efforts, and that all of anatomy which is really learned comes through quizzes and private study.

This is, we think, not quite a just view of the matter. The lecturer ought to be able to tell things in a way which books cannot imitate, and ought to infuse into students an interest and enthusiasm such as he can gain in no other way. The lecturer still has his uses. But that there are defects, and plenty of them, in his methods of teaching anatomy is most apparent. Some of these have been recently discussed in an article by Dr. A. H. P. Leuf (*Gaillard's Medical Journal*, December, 1887).

The criticisms made are mostly such as could only be charged against unintelligent and incompetent anatomists. There are, however, some defects which, it is believed, are common to nearly all American medical colleges. One of these is no doubt the excessive individualizing of the different parts of the body. Too many areas, triangles, subdivisions of organs, ridges, processes, are forced upon the student's attention and memory. His mind, confused with details, cannot grasp general views. Though he knows all the points of interest on the four surfaces, the greater and lesser wings, and the pterygoid processes of the sphenoid bone, he really has but a vague idea of its exact relations in the cranium. He knows, perhaps, every wrinkle on the pelvis, but has no just conception of the mutual relations of the organs inside it.

It is one of the traditions of anatomical teaching that great stress should be placed on the bones. Sir Astley Cooper's advice, "Bones at morning, bones at noon, and bones at night," has expressed the feeling of anatomical teachers for many years. This opinion, however, is of a time when bones and joints and muscles were the best known and best illustrated parts of anatomy, while the true structure of the viscera was much more imperfectly understood. Often the bones still take up a disproportionate amount of time. As medical students cannot be made to master completely all branches of anatomy, each must be taught with due regard to its practical importance. This sense of proportion has been lacking in many anatomical teachers, if we may judge from complaints that occur. The topography, structure, and relations of the abdominal and pelvic viscera are, as a result, often most imperfectly understood, while the layers of muscles on the back may be recited with the utmost glibness. It is stated by hospital examiners that few students graduate with more than a rudimentary knowledge of the nervous system.

While we cannot entirely admire its literary style, we submit Dr. Leuf's summary of the defects which he thinks exist in the present method of anatomical teaching:

"1. The instruction is special, though complete only as regards certain organs or parts of the body.

"2. It is too general as regards other organs or parts of the body.

"3. It is neither the one nor the other as regards still other organs or parts of the body.

"4. It is the custom to generally overlook these relations of organs to one another, which, if properly taught, would be very useful to remember.

"5. There is a general failure to prepare the student's mind with a proper incentive to acquire anatomical knowledge before it is imparted.

"6. Too little is said of the philosophy or principles of anatomy, which, if properly taught, would make remembrance easier.

"7. The failure to always clearly show the relations of anatomy to the other branches of medicine.

"8. Incompetent teachers, or such who, though competent, are indifferent, or have not sufficient time to do their duty."

THE SIZE OF AMERICANS.

SOME interesting statistics, collected a short time ago from hatters, seemed to show that the heads of Englishmen and of Americans were growing larger. Quite recently Mr. Edward Atkinson has collected statistics from clothiers all over the United States, and comes to the conclusion that the whole American, as well as his head, is growing bigger. In any given thousand garments Mr. Atkinson found that the average of all the returns is as follows: Chest measure, 38 inches; waist, 33½ inches; length of leg, inside, 32½ inches; average height ranging from 5 feet 8½ to 5 feet 9 in New England, up to 5 feet 10 for the average at the South and West. A few deductions of weight are given, from which one can infer that the average man weighs between 155 and 160 pounds.

Since the war the people of the South have been more active physically, and in consequence they measure fully an inch more around the chest and waist. The Southerner has comparatively a long leg and a small waist. He measures 37 inches around the chest, 32–33 around the waist, and has a limb of 33 to 34 inches in length. In Texas alone there seems to be a disproportionate increase of waist, giving the impression that the citizens of the Lone Star State are acquiring habits of indolence and ease. The Yankees resemble the Southerners in having long legs and small waists; this anatomical conformation is incorporated in the historic conceptions of Brother Jonathan, and may be considered the anatomical characteristic most common to pure Americans.

In the West, from climatological and ethnological causes, the waists are proportionately larger, and the legs shorter. A Detroit correspondent says: "We notice marked peculiarities in regions where dwell people of one nationality. The Germans need large waists and short legs, the French small waists and legs, the Yankees small waists and long legs, the Jews medium waists and short legs."

NORTHWESTERN MEDICAL AND SURGICAL SOCIETY.—At the annual meeting of the Northwestern Medical and Surgical Society of the City of New York, held December 21, 1887, the following officers were elected: President, Dr. R. C. M. Page; Vice-President, Dr. A. M. Jacobus; Secretary, Dr. Edward S. Peck. The President and Secretary form the Committee on Publication.

News of the Week.

DR. E. G. LORING writes: "A slight misconception occurs in your last issue in regard to some remarks which I made before the Practitioners' Society. It is stated in your report of the proceedings that 'it was worthy of note that nearly all the changes in the eye, in general diseases, had been recognized within the last ten years.' It should be that 'changes had been recognized in the eye, in nearly all the general diseases, in the past ten years.'"

DR. FRANK POTTER, a leading physician of Petersburg, Va., fell dead January 3d, of heart disease, while going into a drug store. He was sixty-five years old.

THEODORE H. COOPER, M.D., a member of the Assembly of New York State of 1865, died at Warwick, on Monday, January 2d, aged fifty-four years, after a short illness.

THE LITERATURE OF GYNECOLOGY in the past eight years, says Dr. Skene, has been enriched by 807 books and 7,505 journal articles and pamphlets. This makes about 2 books and 18 articles a week.

AN ANTIDOTE TO SERPENT'S VENOM.—Dr. H. C. Yarrow confirms the view of Dr. Josso, that jaborandi has decided antidotal powers to serpent venom.

ARSENIC CANCER.—Mr. Jonathan Hutchinson, after referring to the fact that arsenic, when long used, may lead to the development of soft corns on the palms or soles, states that, in his belief, arsenic may also produce, or at least be an exciting cause of, epithelial cancer. Sir James Paget held the same view. This will be joyful news to our homœopathic brethren.

THE THERAPEUTIC VALUE OF HYPNOTISM.—A correspondent asks whether hypnotism is a practical therapeutic measure. We answer decidedly, no. Only persons of a weak or unstable nervous system are amenable to hypnotic influence. This influence is itself bad, for it increases the natural nervous irritability. As a therapeutic measure it answers sometimes to relieve symptoms in the hysterical or insane, and we have known it sometimes to relieve neuralgias, sea-sickness, and spasmodic conditions. Details of the methods of its employment will be found in an article on the subject by Dr. C. L. Dana, in THE MEDICAL RECORD of July 21, 1881.

REDISCOVERY OF COW-POX.—Professor Crookshank has discovered an epidemic of cow-pox in England. It was at first thought to be the so-called scarlet fever of cows.

THE GOVERNOR'S MESSAGE.—Governor Hill in his annual message, this week, recommends the abolition of the State Board of Charities and the concentration of its powers in a single officer, and the abolition of the State Board of Health and the vesting of its powers in one official The object involved in these two measures is the concentration of official power and responsibility in some one responsible head, by which the efficiency, usefulness, and economy of the public service will be increased.

Blood and Buttons.—Beef's blood is being used in Chicago to make buttons.

The Hospital Saturday and Sunday Collection had at date of writing reached the sum of about ten thousand dollars.

Another Report on Quarantine Abuses.—The report of the Committee of the New York Academy of Medicine, on quarantine abuses, has been made to the Mayor. The members of the committee were: Dr. C. R. Agnew, Dr. E. G. Janeway, Dr. Stephen Smith, Dr. A. Jacobi, Dr. T. Mitchell Prudden, Dr. Herman M. Biggs, and Dr. Richard H. Derby. Their investigation began, December 19th. They call attention to the fact that the quarantine establishment is in the custody of the Board of Quarantine Commissioners, and that the health-officer has no other control than that of police. No opinion is expressed regarding the advisability of placing quarantine under charge of the general Government.

The Fees of the Health-officer.—A bill has been introduced into the State Legislature reducing the fees of the health-officer of this port and placing him on a salary of $10,000.

Twins, one Black and one White.—Dr. Newton Hill, of Pickensville, Ala., sends to the *Medical and Surgical Reporter* the report of the following case: "A black negro girl, about eighteen years of age, gave birth to twins at seven months, one of which was as black as the *ace of spades*, and the other as white as any white child I ever saw. This girl has been engaged as nurse in a white family a part of the year, but she has associated with both white and black. Both cords were attached to same placenta. Is this merely a freak of nature, or is it possible that they have different fathers? I would like to have the opinion of some of the brethren." A similar case is reported in Flint's "Physiology," and it is believed to illustrate the fact that there can be such a thing as superfecundation.

Concerning a Cerebral Tumor.—A lively discussion has arisen in the Irish Academy of Medicine over a case of cerebral tumor which, it is claimed, should have been operated upon and removed. The patient suffered from sensory aphasia, and local spasmodic and paralytic troubles. It was agreed that she had a tumor, but whereas Mr. Wheeler thought that it was situated immediately posterior to Broca's space, and might, without reasonable doubt, be got at by the trephine, Mr. Franks, backed by his consultant, Dr. Head, believed that it might be anywhere, that it would probably not be reached by operation, and—if reached—would be probably found to be solid and not relievable. The patient died unoperated, and on post-mortem examination a fluid cyst was found in the temporo-sphenoidal lobe, about an inch behind Broca's space. Now Mr. Wheeler claims that the patient's life might have been saved by an operation.

A Sanitary Journal Sued for Libel.—The *Annals of Hygiene* has been sued for libel by a certain "Sparkling Distilled Water Company" of New York City. The suit grows out of the publication in the December issue wherein it was stated that the water which this company places upon the market did not, upon analysis, prove to be the same as that which they claimed in their published analysis in The Medical Record. The *Annals of Hygiene* is the official organ of the Pennsylvania State Board of Health.

Can a Woman Conceive after having Gonorrhœa?—To this question, propounded in the *Medical Brief*, a number of affirmative answers are, of course, given. Mr. James Ward Scott writes: "Assuredly; why not? Miss ——, aged eighteen, among my first calls, had a 'blooming case.' At twenty married a Baptist preacher; settled down in Virginia; *eight children*. Mrs. ——, widow, fell from grace journeying to St. Louis in sleeping-car; beautiful case. Married second time, and had *twins* eleven months after. Could give many more cases, but the two mentioned will answer. Every country doctor knows that gonorrhœa will not prevent conception."

The Blood in Tuberculosis has been found, by Freund, of Vienna, to contain a peculiar body resembling cellulose. This discovery of cellulose has been confirmed by Dr. Kabrhel, of Prague. Dr. Freund also finds in the blood of the tuberculous an excess of potassium salts and decrease in phosphoric acid and sodium salts.

Microbes and Expired Air.—The expired air is optically pure and contains no microbes. Respiration purifies air, therefore, so far as microbes are concerned.

The New England Cremation Society, organized in Boston two years ago, has disbanded, because the Bostonese refused to be cremated.

Homœopathic Dosage.—The homœopaths of this city are prescribing antipyrine in fifteen-grain doses.

Ptomaines in Puerperal Fever.—Dr. L. Bourget, in an inaugural dissertation (*Thèse de Genève*, 1887), states that he has succeeded in isolating certain ptomaines from the urine of several women suffering from puerperal fever. Having studied these substances both from the chemical and biological point of view, he has arrived at the following conclusions: 1. In puerperal fever, the urine contains some bases of a very toxic nature. 2. These toxic principles seem to attain their greatest development during the acute period of the disease. Their quantity diminishes with decrease of the morbid phenomena. 3. The chemical bodies in question produce in animals (frogs and guinea-pigs) exactly the same disturbances as are brought about by certain poisonous ptomaines. 4. Various organs of a woman who had died from puerperal fever were also found to contain some toxic substances which, in their biological effects, closely resembled the toxic bases obtained from the urine. 5. All those extractive products found in the urine and organs gave all the general reactions of vegetable alkaloids and ptomaines. 6. In a chemical analysis for medico-legal purposes, they may be mistaken for a vegetable alkaloid, or, at least, may interfere with the characteristic reaction of the latter. 7. Such grave mistakes can be avoided by carefully purifying the examined material after Stas-Otto's methods.—*British Medical Journal.*

Reports of Societies.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, December 26, 1887.

LAURENCE JOHNSON, M.D., PRESIDENT, IN THE CHAIR.

DR. J. S. WARREN read a very acceptable

BIOGRAPHICAL SKETCH OF WM. M. CHAMBERLAIN, M.D.

THE PRESIDENT announced the death of C. Dixon Varley, M.D., and Thomas J. I. Ford, M.D.

DR. G. H. FOX then read a short paper on

THE VALUE OF RESORCIN IN THE LOCAL TREATMENT OF ACNE.

The chief divisions which he made of acne were, first, that form in which the vascular element was a well-marked feature, and in which local treatment was *not* indicated, but, rather, general tonic and hygienic; and, second, that form where the disease was indolent, with dilated glands and ducts and comparatively little congestion of the skin, and in which stimulating applications could be used with advantage.

Remarks were made by Dr. Lewis and the President.

DR. J. LEONARD CORNING then read a paper (see p. 3) on

THE TREATMENT OF CHOREA BY CEREBRAL REST,

in which he first referred to the history of the disease and its different names. He thought it quite impossible to distinguish chorea major as a separate disease, and included in his paper only the phenomena of what was known as chorea minor. The clinical phenomena of the affection were then described—the movement of the muscles of the face and other parts of the body, the disturbances of psychical functions and sensation, etc. In the majority of cases the disease terminated in complete recovery. He also spoke of the relations existing between rheumatism and scarlatina and chorea, and of other causes, such as fright, peripheral irritation, which, if not a direct cause, might favor its development in neurotic subjects, as seen in phimosis and some ocular troubles.

After referring to the pathology of chorea, which in most cases was a functional disturbance of the cerebral cortex, he passed to the treatment, and the chief indication was

TO ALLAY CEREBRAL ERETHISM.

The great factor in securing that end was prolonged rest. To secure that he endeavored to remove all sources of irritation, all peripheric irritation, especially that from light and sound, and gradually increased the amount of sleep by the use of the bromides and other sedatives. It had been his method to put these patients fully under the influence of the bromides, keep them secluded in a dark room, administer farinaceous diet, arsenic, etc. He had used galvanism with benefit, and a helmet, arranged so that the current was applied through ice-cold water, was exhibited.

DR. WEBSTER referred to a case of chorea laryngis, and then spoke of chorea in its relation to eye-troubles. A distinguished physician in this city had claimed that a large proportion of cases of chorea could be cured by

CORRECTING ERRORS OF REFRACTION.

Dr. Webster's experience had led him to believe that a certain proportion of cases had been benefited, and that possibly a small proportion could be cured, by that method of treatment.

Since his first paper was published, the same physician had claimed that lack of proper balance in the ocular muscles was a prominent cause of chorea, and that by cutting the muscles just enough to restore that lack the disease could be cured. Dr. Webster had had a single case in which this lack of balance in the ocular muscles existed. There was insufficiency of the externi. He divided one of the interni, and the patient claimed that she experienced great relief at once. Two or three months afterward he divided the other internal muscle, and when he saw the patient last she was not entirely cured, although she said that she was two-thirds or three-fourths cured, and he felt, to a certain extent, satisfied with the result. Doubtless the removal of the constant strain had had a good effect upon the general nervous system and, indirectly, upon the chorea.

DR. KOPLIK had treated a large number of cases of chorea by giving the patients perfect rest. Most of his patients had been children from five to twelve years of age, and many of them had had their condition aggravated by school-work, or by the harsh reproval of parents when at home. He had therefore, as much as possible, kept them from the other members of the family, had them eat by themselves, etc. He doubted the efficacy of confinement in a dark room, because of the possibility of frightening the children, although he had had no experience in applying the suggestion.

He believed that the treatment of chorea would be placed upon a better basis than it now has, were the views of Meynert kept in view, that the disease did not affect all subjects, but that there was a predisposition to other nervous diseases, as well as to chorea, in those who had the affection. Rest and improvement of the general condition were probably steps in the direction of solving the vexed problem of the pathology of the disease. He believed that special drugs did not help very much in effecting a cure.

DR. FOX spoke of the difficulty of applying galvanism through the hair, and the liability of the current to produce pain in the bare spots, as he had seen in cases of alopecia areata which he had attempted to treat with electricity.

DR. CORNING said that the hair was an obstacle, but with the wet sponge in the helmet, and the hair also wet, he had not encountered any serious impediment to its satisfactory use, although the patients did feel it more in some places than in others.

Of course, it would be objectionable to place some children in a dark room, but he always bromized his patients, which allayed the fear as a rule, and it was astonishing how much sleep could be gradually increased in that way, and the patients also increased in weight rapidly, as a rule.

THE PRESIDENT referred to two cases that showed a close relation between chorea and rheumatism,

TOO CLOSE TO BE ACCIDENTAL.

He believed that the farinaceous diet recommended by Dr. Corning was objectionable in many cases, as the patients required the most sustaining food that could be given, besides iron and other tonics. He had not been able to use arsenic in as large doses as Dr. Corning had mentioned—eighteen drops of Fowler's solution three times a day—and he also thought that the use of the bromides as suggested was rather indiscriminate. According to his experience, choreic patients showed rapidly the deteriorating influence of the bromides.

DR. CORNING said that he only carried the bromides far enough to quiet the patient, and he had found that when that had been done the disease yielded better to the treatment by arsenic. He had no doubt that there was a close relation between rheumatism and chorea, and regarded the statistics of the French writer whom he had quoted as unreliable.

DR. CARPENTER spoke of the occurrence of relapse, and of the belief of some excellent observers that arsenic had but little influence in effecting a permanent cure.

DR. CORNING said that he would not attempt to treat the very severe cases of chorea in the manner he had indicated. The question of relapse was a very important one, and should never be lost sight of.

NEW YORK NEUROLOGICAL SOCIETY.

Meeting held, December 6, 1887.

THE PRESIDENT, DR. CHARLES L. DANA, IN THE CHAIR.

DR. WAITZFELDER presented a case of

CIGAR-MAKER'S CRAMP.

The patient was a man, thirty-eight years of age, and had been a cigar-maker for twenty years. He was first seen by the speaker six months ago. Six months before this he had commenced to notice a stiffness and awkwardness in forming the head of the cigar. This required a rotary motion of the thumb and index-finger. At first he was able to substitute his middle finger in this manœuvre, but later the stiffness extended to this and finally to the little finger. When first seen there was some anæsthesia of the skin and tonic spasm of the flexors of the fingers. These contractures were partially relieved by rest, although they never entirely disappeared. They were aggravated by any effort to work at his trade and by changes in temperature either to heat or cold. A short time ago the patient had tried varnishing, work which requires only coarse motions of the hand; but was obliged to give it up. The patient had been under treatment for six months with galvanism, faradism, strychnine, etc., without improvement. Regarding the lesion as central, the speaker suggested stretching the radial nerve with the object of inducing atrophy in the spinal cells, which might be considered the source of irritation. As Dr. Seguin had seen the case, his opinion was requested.

DR. E. C. SEGUIN saw nothing which would distinguish the case from one of aggravated professional spasm. He regarded such dyskineses of central origin and would not favor nerve-stretching. His experience had, in fact, been discouraging in any treatment for professional cramp. A case of

WAITER'S CRAMP

had come under his observation. He mentioned it, because rare. The man had been a waiter for fourteen years, carrying plates in the manner of his class until reaching a stage when he broke dishes and spilled their contents over the guests.

Dr. Seguin read a paper upon

THREE CASES OF HEMIANOPSIA

of peripheral or neural origin; with a study of the symptom hemiopic pupillary inaction, its diagnostic value, etc.

All of the cases were supposed to have a neural peripheral lesion. All presented the pupillary reaction hinted at by Von Graefe and described by Wernicke as the hemiopic pupillary reaction, a symptom never yet observed or described in this country.

CASE. I.—Was first seen October 26, 1887. Six years previously the patient had commenced to suffer from headache, mostly frontal, also nausea and vomiting. Two years previously he had suffered from more or less constant pain. For the last few months the headache had been less, but he had lost vision in the left eye. No history of syphilis had been obtained. On examination the right visual field showed temporal hemianopsia outside the point of fixation. The visual field of the left eye was completely blind. Vision was at this time, $R=\frac{20}{200}$, $L=0$. Light thrown into the left eye caused no reaction in either pupil. If thrown into the right eye in the optical axis good reaction in both pupils occurred. If the light was moved nasalward reaction was obtained in both pupils, also if moved temporalward within an angle of sixty degrees. If thrown farther toward the temporal or blind side, no reaction in either pupil occurred. The centripetal portion of the arc controlling pupillary reaction was complete only in the right eye, while the centrifugal portions were perfect in both eyes.

The lesion in this case is probably one of the chiasm, destroying both fasciculi for the left eye, and the fasciculus cruciatus for the right eye.

CASE II.—Was one of typical temporal hemianopsis with darkness also of the nasal quadrant upon the left side. The patient, forty-one years of age, was referred to the author by Dr. David Webster.

In 1866, the patient had noticed occasional headaches, with increasing failure of the left eye. There was diplopia at that time. If two objects were present, the patient saw three. Light attacks of vertigo were complained of. There was no history of syphilis in the case. The patient was first seen by the author, November 11th. The right eye showed the vertical line of separation passing through the point of fixation. This was the first case in the author's experience of either central or peripheral origin of which this has been true. There was right hemiopic pupillary reaction. If light were thrown from the temporal side at an angle more oblique than sixty degrees no reaction occurred. If thrown from the nasal side or directly into the eye, slight reaction of both pupils was obtained. In the left eye, slight reaction occurred only to central illumination. Vision, $R=\frac{8}{200}$, $L=\frac{20}{50}$. The latter was an interesting finding, as the left eye, with the better vision, had a smaller field than the right eye, showing that vision is not measured by the geometrical extent of the field, but rather by the general state of nutrition of the optic nerve.

The lesion in this case involved both fasciculi cruciati and the ventral or inferior half of the fasciculus lateralis of the left eye. A test made, December 16th, showed that color-perception was normal in the preserved half and quarter fields of vision.

CASE III.—Was twenty-five years of age, also had been referred to the author by Dr. Webster from the Manhattan Eye Department. The case was first seen, October 10, 1887. The patient had commenced to suffer from loss of vision two years previously. At the date of examination the right eye was completely blind. There was general loss of strength, but no etiology of injury and no history of syphilis. There was no paralysis, no loss of equilibrium. The dynamometer showed twenty-three degrees in the right hand, twenty in the left. At a subsequent examination the left eye showed typical temporal hemianopsia. Left vision was good. Can read No. 1 Jaeger at seven inches.

The lesion in this case involves the fasciculus cruciatus for the left eye and irregularly both fasciculi for the right eye.

The author then referred especially to the symptom common to the three cases called by Wernicke

HEMIOPIC PUPILLARY REACTION,

but which he would designate as hemiopic pupillary inaction; and its diagnostic value in hemianopsia of central or peripheral origin. The optic arc consists of the retina, especially the macula, and the optic nerves, for its centripetal portion; the anterior group of the corpora quadrigemina with the nuclei of the motor oculi nerves, the motor oculi, the ciliary nerves and the iris, for its centrifugal portion. Contraction of the whole iris follows stimulation, because the termination of the ciliary nerves is plexiform in arrangement. The path may be broken by lesion of the centripetral portion, by lesion of the reflex centre (or optic lobes), or by lesion of the centrifugal path. The termination of this—the iris—may be immobile from iritis. In the cases reported, the symptom was observed with temporal hemianopsia. If a pencil of light were directed in the optic axis or moved nasalward so as to strike upon the temporal or normal half of the retina, good reaction was obtained; also if moved temporalward up to an obliquity of sixty to seventy degrees; but if it entered at an angle of forty to sixty degrees from the horizontal, no reaction was obtained. The light experiment is not exact, because it is impossible to focus exactly the pencil of light. By focussing nearly in the optical axis, crossing of the rays and diffusion with reception upon the temporal or sensitive portion of the retina occurs. Without this diffusion inaction of the pupil would be noted as soon as the rays of light struck the nasal side of the field, and the experiment would be as exact as the perimeter test.

In making the examination the patient should be in a dark room with the gas jet or lamp behind him in the usual position for ophthalmological examination. The patient should be directed to look toward the farther side of the room, and a faint light from a plane or large concave mirror held out of focus thrown into the eye. Relative relaxation of the iris is thus obtained. A beam of light focused by the ophthalmological mirror is then thrown into the pupil from its optical centre and from various angles neuralward and temporalward, and reactions noted. It is especially important that the patient should look at a distant object, the same was true for ophthalmological examination in tabes, etc.

The author then added a number of rules for determining the location of the lesion in cases of hemianopsia.[1]

Dr. Græme Hammond presented

A CASE OF BITEMPORAL HEMIANOPSIA,

for Dr. C. H. Brown.

The patient, a woman, thirty-seven years of age, August 10, 1887, was suddenly seized with pain in the right eye, the sight of which was lost. The pain spread to the left eye and in three minutes she was totally blind. The pain continued spreading over the head to the base of the skull. The patient was in bed six weeks. November 15th she commenced to walk a little, and under the iodide treatment vision returned so that she could see an object if within two feet of the eye. She can now read newspaper headings, but effort to do more than this gives pain. Examination showed obscuration of the nasal half of the field, covering the point of fixation in both eyes.

Dr. Dana had seen the fields drawn by Dr. Francis Valk, and the obscuration was very marked. Dr. Seguin was able to give a satisfactory demonstration of hemiopic pupillary inaction in this patient.

Dr. Brill proposed three divisions for cases of hemianopsia, namely: into those of prosencephalic, mesencephalic, and peripheral origin.

Dr. Starr suggested that the society owed its thanks to Dr. Seguin for a series of three papers upon so interesting a subject. The symptom had been known and its lesions tabulated especially by Wernicke in his "Gehirnkrankheiten," but not before in the English tongue. The symptom had to be searched for carefully. The speaker referred to the fact that Ferrier, in "Brain," Vol. VI., makes the escape of the macula a diagnostic point, stating that where the lesion is located in the chiasm and tract, central vision is impaired; that where it is located in the cortex, or between the thalamus and the cortex central vision is not impaired, and had formed his new diagram in the second edition of his "Functions of the Brain" upon this theory, according to which central vision should have been impaired in all of the reported cases.

Dr. Seguin closed the discussion. He found clinical records opposed to Ferrier's classification. For the dividing line hardly ever passed through the point of fixation in any form of hemianopsia, and he failed to get light on the escape of the macula by any theory of decussation. He was rather inclined to think it dependent upon the structure of the macula, which was somewhat ganglionic in character and markedly different from that of the remainder of the retina. Before Von Gudden, Brown-Séquard had demonstrated the existence of a local mechanism for the iris contraction in lower animals, but there was no evidence that such a mechanism was active in the human eye.

Dr. Noyes then presented specimens of

COMPOSITE PORTRAITURE IN THE INSANE.

A composite taken from eight general paretics was exhibited. This showed in a marked degree the washing out of the lines of the face. Incidentally, Dr. Noyes also exhibited the college composites recently published.

Dr. Seguin suggested that the Vassar composite had a more womanly character than that of the Harvard Annex.

Dr. Birdsall agreed in this opinion. The Harvard composite figured an intellectual rather than a womanly being.

The meeting adjourned.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, December 22, 1887.

SECTION IN OBSTETRICS AND DISEASES OF WOMEN.

E. L. Partridge, M.D., Chairman.

Dr. M. Putnam-Jacobi read a paper on

THE NATURE AND DANGERS OF INTRA-UTERINE MEDICATION,

in which reference was made first to a paper read in January, 1885, when the opinions of forty-five eminent gynecologists were given, with forty in favor, and five opposed to the method. The most recent statistics on this point showed that the ratio for and against had changed somewhat.

The objections which had been urged against intra-uterine medication were that it was dangerous, inefficacious, or superfluous, or all three together. After referring to these briefly, the author of the paper proceeded to inquire more precisely concerning the series of clinical phenomena which followed the employment of caustics, as the paper did not consider any intra-uterine medication which was not caustic. The central purpose of the method was surgical, and for the removal of diseased tissue.

After a caustic was applied, the first effect was contraction of the muscular fibre of the uterus, attended by pallor of the tissues. The second effect was bleeding from the mucosa, and that might be considerable. Third, during several hours after the application there was a painful sensation, varying in intensity. Fourth, cramps might not occur after the application, but a diffused pelvic pain coming on at the end of fifteen minutes or an hour, and lasting a variable length of time. This implied dilatation of blood-vessels and hyperæmia, with active afflux of blood to the parts. Fifth, from thirty-six to forty-eight hours after an application, bleeding from the uterus occurred, accompanied by discharge of shreds of tissue, which was the eschar formed by the caustic. Sixth, after the cessation of the secondary hemorrhage, the leucorrhœal discharge existing previous to treatment frequently diminished, and coincidently the pelvic pain and the first menstruation were less painful in favorable cases. Sometimes an unusual painful menstruation followed first, which was regarded as unfavorable.

The next inquiry was, How did the treatment modify the metritis? The essential of all uterine therapeutics was to increase the arterial circulation in the pelvic tissues for the purpose of

DISSIPATING VENOUS HYPERÆMIA.

The difference between the active hyperæmia determined by cauterization and that resulting from disease was then pointed out, and the effect of the intra-uterine medication upon the next menstruation described.

The theory of the action of any application to the endometrium was then discussed, and its effect upon the physiological process sustained in the uterus, which made intra-uterine so surprisingly different from every other form of cauterization. The endometrium was not to be compared with mucous membrane, because it possessed the peculiarity of reproduction. It was that peculiarity which made it impossible to treat this as other chronic inflammations were treated.

---

[1] For the complete paper with Diagrams *vide* Journal of Nervous and Mental Diseases, December, 1887.

The object desired was to modify the menstrual process, which was nearly continuous, and to do that the short interval must be seized, with the expectation that the effect of the application would extend through the time of the following menstrual period. Attention was then directed to the dangers of the method. The present paper was based upon fifty cases, in which cure was produced in thirty-nine without accident. In five cases accidents occurred. In two cases cure was effected in spite of the accidents. One death occurred. The details of the five cases were given.

Of all the dangers of the method none was so important as

APPROXIMATION TO THE MENSTRUAL PERIOD.

The period of danger began ten days after the close of menstruation, although in many cases the application might be made without danger much later in the month. Never make two applications in one month until the tolerance of one had been established, and the second application, as a rule, was to be milder than the first. It was very exceptional that three applications could be made in one month. At the end of three months it was advisable to suspend the treatment for two or three months. In the great majority of cases it was unsafe to make the application in the office and allow the patient to go; for she should remain in bed from six hours to six days.

INTRA-UTERINE MEDICATION SHOULD BE REGARDED AS A SURGICAL OPERATION.

The agents which the author of the paper had employed were iodized phenol, carbolic acid, and nitric acid. The treatment was indicated in fundal endometritis; endometrial catarrh always associated with parenchymatous metritis complicated by displacement, and always attended by cervical catarrh; metritis quite often with little or no catarrh, and in the text-books regarded as incapable of treatment in this manner. Peri-uterine inflammation might be said to forbid intra-uterine medication; but if it was secondary to endometritis, the method might be indicated. Finally, intra-uterine medication was to be regarded as only one part of a complex treatment for uterine disease.

Dr. W. Gill Wylie fully agreed with much that had been said in the interesting and instructive paper, but there were some points on which he was not in full accord with the writer. He was pleased to hear her speak of the application as a surgical procedure, because it was one, and he thought that that fact accounted for the lack of success it should have.

His practice had been one in which he had used intra-uterine medication a great deal, and he invariably kept a case under observation a long time

BEFORE MAKING AN APPLICATION.

Almost without exception, the cases should have preparatory treatment. He agreed with the author of the paper entirely in the statement that one thing to be accomplished was to improve the circulation of the pelvic tissues, certainly the uterine tissue. He was satisfied that preparatory treatment, by means of boro-glyceride, or the alum and glycerine mixture, should be kept up for at least one month before making an intra-uterine application. He never made an application without testing whether the uterus was dilated or contracted. If contracted in the least, he used dilators that enabled him to make a thorough and complete application, and also to secure perfect drainage, which was as important as the application itself. The old mucous plug was so readily displaced by slight dilatation that it did not cause the least trouble.

Another objection to the paper was the recommendation of the use of strong acids. He believed that the cases were exceedingly rare in which anything stronger than carbolic acid was required. In very old cases a mixture of carbolic acid and iodine might be used. He preferred to divulse and use the milder agents, and, so far as his own practice was concerned, two winters would pass probably without a single accident after intra-uterine medication.

By the preparatory treatment, he was able to adopt the method in his office or at the clinic. He might dilate slightly at the time of the application, but he never dilated unless he was thoroughly acquainted with the patient and the case.

INTRA-UTERINE MEDICATION SHOULD NEVER BE ADOPTED IN ACUTE CASES.

Keep such cases under observation until they become subacute.

It was also very essential to make the application through a cervical tube, as without that precaution not more than one-third or one-half of it ever reached the uterine cavity.

Dr. S. Baruch said it had been justly stated that intra-uterine applications were surgical procedures, and therefore he believed that the same course should be pursued as in similar conditions elsewhere, as in the treatment of bone, for example.

Three years ago he read a paper on the "Therapeutical Significance of the Cervical Follicles" (*New York Medical Journal*, 1885), in which he endeavored to show that all those diseases of the uterus classed under metritis, with or without catarrh, were most successfully treated by treating those follicles. His method was, when the disease was in the cervix, to open with a narrow bistoury, and with a sharp curette to destroy as much of the glandular structure as possible. He also treated intra-uterine catarrh with the sharp spoon. At the time he published his paper he was in doubt somewhat as to what would be the ultimate effect of removal of the mucosa, but he had since had ample evidence that the entire removal of the mucosa did not prevent its reproduction. Düvelius, Martin's assistant, had demonstrated that it was impossible to remove the glandular structure entirely, so that it would not be reproduced, and had reported sixty cases in which the woman became pregnant subsequent to thorough removal of the mucosa. It seemed to him, therefore, that thorough curetting was much more in accordance with modern surgical ideas than the repeated use of caustics. It was the practice which he had pursued during the last three years with satisfaction.

Dr. P. F. Mundé took occasion not long ago to publish his views on this subject, and he did so because he thought the tendency was to drop intra-uterine medication entirely. He believed that it had a position which it would always retain. It was a surgical procedure, and dangerous, as might be the introduction of a sound, or even a digital examination. Therefore, it must be undertaken with proper precautions. The applications should be made at the house of the patient, although probably, in the great majority of cases, it was impossible to observe that precaution.

There were three main indications for intra-uterine medication: First, intra-uterine catarrh, extending from the cervix to the fundus; second, subinvolution or hyperplasia, with or without catarrh, where it was desirable to reduce the size of the uterus; and third, to control hemorrhage.

For many years he had used the milder agents, mentioned by Dr. Wylie, but his results had not been as satisfactory as he would like to have, and he had sometimes felt that the applications were almost useless. At the same time, with proper precautions, he had been fortunate enough to escape entirely any bad consequences, except in two cases, where cellulitis followed—in one due to imprudence probably, and in the other the cause was not apparent.

FINDING THAT MILD REMEDIES DID NOT ANSWER,

he had placed his patients in bed, dilated the canal, if necessary—not much dilatation being required in chronic uterine catarrh—so that the largest uterine applicator with a pledget of cotton could be readily introduced, curetted with a dull instrument, and then swabbed the entire endometrium with a saturated solution of chloride of zinc, repeated two or three times perhaps, or until no bloody fluid oozed out of the uterine cavity. Then pack the vagina with iodoform or vaseline cotton. Keep the patient in bed two or three days, and apply an ice-bag to the abdomen for the first twenty-four hours. The next application was made at the office, but not within two weeks, and then a solution of one drachm to the ounce was used, or nitrate of silver of the same strength. The subsequent applications were made once a week. During the last two years he had succeeded much better than he did formerly, when he made half a dozen or a dozen stimulating applications. Of course, some patients would not submit to the procedure, and then the milder measures had been used.

For some time he had not used the cotton-wrapped syringe, because he had come to regard it as not perfectly safe.

For hemostatic purposes he curettes, and then plugs the uterine cavity with cotton saturated with subsulphate of iron and glycerine, equal parts, and he had never seen any bad results from the treatment. Attach a string and direct the patient to remove the plug at the end of twenty-four hours.

We should be able to practise intra-uterine medication with complete safety in the office, but had not reached that point yet. Iodoform and alum pencils, five grains each, covered with gelatine, did good in mild cases, and seldom produced discomfort. They served very well for the treatment after the use of the severe caustic. Possibly galvanism would prove to be the remedy that could be used with greatest safety.

Dr. Cushier had employed intra-uterine medication during the last ten years, with good results in young, unmarried women, when the chief symptom had been dysmenorrhœa, or pelvic pain with the menstrual period; also in chronic metritis, subinvolution, and where there were reflex symptoms from pelvic disorder not due to either uterine displacement or ovarian disease.

Her largest experience had been in the cases in which the prominent symptom had been severe dysmenorrhœa, and then it had not been employed until other means had failed; yet there had been but few cases in which the result had been unfavorable, and in many complete cure had been effected. Pelvic inflammation had not occurred in any case since the applications had been made with the precautions advocated in the paper; that is, never after ten days subsequent to menstruation, and never within ten days of the next period. Thus far she had not seen any necessity for using stronger agents than carbolic acid and iodized phenol; perhaps had been fortunate enough not to have seen the intractable cases mentioned this evening.

THE APPLICATIONS WERE NEVER MADE EXCEPT AT THE HOUSE OF THE PATIENT,

and it depended entirely upon the amount of reaction whether she should remain in bed one, two, or three days.

Nor did she believe that the results were so good as they might be if the patient was permitted to get up sooner than two or three days after the application. The benefit in some of the reflex cases had been very marked indeed. In women who had not borne children, she never resorted to intra-uterine applications until other means had failed, because she had found that the reaction was much more marked, and also that other remedies were much more effective than in women who had borne children.

Dr. Malcolm McLean had narrowed the agents he had employed down to strong carbolic acid. If applied thoroughly it would do what the stronger caustics had had claimed for them, without the risk attached to their use.

He used a ninety per cent. solution of carbolic acid, introducing just enough into the uterus to touch the diseased surface. It was very important to have

A WELL-DILATED CERVICAL CANAL,

and then, if a tube was used, a thorough application could be made. The time for making the applications, that is, within the ten or twelve days succeeding menstruation, he regarded as important. As to the necessity of the patient being at home, he had not insisted upon it, although it would be a safe precaution to take. He had not had cause to regret making the application in the office, although he had insisted that the patient go home at once and go to bed for a short time. He believed that in carbolic acid we had such a valuable remedy for these cases, so much safer than any other, that we should confine ourselves to its use as much as possible.

Dr. H. J. Boldt had been in the habit of making intra-uterine applications up to within a few days of the menstrual period, and had not had any accidents. He indorsed the statement that the application should be regarded as a surgical procedure, and that it was dangerous if proper precautions were not observed. The preparatory treatment he regarded as one of the most important points, and when the susceptibility of the endometrium to irritation was well known, intra-uterine medication could be adopted safely in office practice. The cervical canal must be dilated so as to give free drainage. In old cases he used the curette. He had used the cotton-wrapped syringe without accident. He had not employed strong caustics, but had not hesitated to make two applications a week, beginning a few days after menstruation and continuing up to within a few days of the next period. He had used galvanism only in private practice, but had found that certainly not above fifteen milliampères could be employed.

Dr. A. F. Currier thought it important to keep in mind the fact that there was a great difference in the tolerance of patients with regard to intra-uterine medication, and, therefore, no fixed rule could be laid down applicable to all cases. It was probable that where it was used without regard to precautions it not only did no good, but did harm. Without the precaution of having the canal open, it could not reach the endometrium. He had seldom seen dysmenorrhea benefited by the applications. In cases of hemorrhage what was done must be done at once, and in subinvolution and other chronic conditions he had found but little need of long preparatory treatment. He used carbolic acid with iodine to the exclusion of almost everything else, except a strong solution of nitrate of silver. He had used electricity in cases of endometritis and sterility, with satisfactory results, and

CONCEPTION HAD FOLLOWED IN TWO CASES.

Dr. Putnam-Jacobi, in closing the discussion, said that the question of preparatory treatment should not have been omitted in the paper, as she never adopted intra-uterine medication without two or three months acquaintance with the patient. The question of drainage, also, was important, and the applications should never be made in cases of displacement. The substitution of curetting, as suggested by Dr. Baruch, for all other methods of treatment, she thought was inapplicable, because there were two conditions which must be taken into consideration: first the thickness of the diseased endometrium, and second, the degree of existing peri-uterine trouble. It was not intended in the paper to discuss other methods of medication or particular agents to be employed, but the effort was to attempt to investigate the theory of the action of any application made to the endometrium, and also to correlate observed facts with physiological processes sustained in the uterus. The physiological process seemed to have been overlooked entirely in the discussion. The impossibility of treating this as other inflammations were treated was one of the points which she insisted upon; that the beneficial results of intermittent treatment could not be explained without the series of phenomena developed outside of the uterus; and that the question of danger depended upon the phenomena in that invisible locality.

A remark made by Dr. Cushier should be emphasized, and that was with regard to

REST AFTER THE APPLICATION.

If the patient walked about, there was a possibility of the development of intense hyperæmia which would prevent arterial tension, the most important condition to be obtained.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE OUT-PATIENT QUESTION—PROVIDENT DISPENSARIES—ANOTHER SUCCESS FOR VISCERAL SURGERY—PNEUMO-PARESIS—THE LATE SIR GEORGE BURROWS, BART.—THE ROYAL COLLEGES AND THEIR PETITION TO THE PRIVY COUNCIL.

LONDON, December 17, 1887.

AT the larger hospitals the out-patient question continues to be a thorny subject. The expense of out-patients is, of course, trifling compared with that of the in-patients, who are boarded and lodged at the cost of the hospital. Nevertheless, where the out-patients are numbered by hundreds, the cost of the medicines supplied to them helps appreciably to swell the total of the hospital drug-bill. The unfortunate physicians and surgeons, also, who have to drudge away—not merely for a year or two, but frequently for a long term of years—in crowded out-patient departments, could say something as to the drawbacks of having too large a clinic. Careful scientific observation of cases is simply impossible where they have to be seen against time. At St. Bartholomew's Hospital, the late Mr. Wormald served for about a quarter of a century as assistant-surgeon before becoming full surgeon. Of him it was said that he was so good as an assistant that it was a pity he ever was promoted. While holding the subordinate position he actually became President of the College of Surgeons. That was many years ago, and probably no such abuse is likely to occur again, but I have known sixteen years' out-patient work done before charge of in-patients was obtained. One very promising scheme for relieving the chronic congestion of out-patient departments is the establishment of provident dispensaries in larger numbers throughout the metropolis. Many such institutions already exist, and are doing much excellent work in their respective neighborhoods, but it is suggestive that many more might with advantage be founded. A wage-limit is, of course, an essential. A great difficulty in working these institutions is to make the classes for whom they are instituted understand and adopt the provident principle. Many of the poor feel a great reluctance to pay money down in advance for future possible medical attendance. If the latter is not required they regard their subscription as wasted. The Medical Attendance Organization Committee has done good work in connection with this subject. At a recent somewhat stormy meeting a resolution accepting a scheme of provident dispensaries was proposed by Mr. Timothy Holmes and carried by a large majority. A second resolution, proposed by Mr. Bonsfield, and expressing approval of the co-operation of hospitals with provident dispensaries, was carried unanimously.

A remarkable example of successful visceral surgery was detailed before the Clinical Society, at its last meeting, by Mr. Edmund Owen. A married woman, aged thirty-four, was admitted into St. Mary's Hospital under the care of Dr. Broadbent, on account of right hypochondriac pain and constant sickness. There was great fulness, with dulness on percussion reaching from the fourth rib nearly to the umbilicus. The right lung was elevated and compressed. The hepatic tumor was smooth, hard, gave no wave on impulse, and did not move with respiration or with any change of position on the part of the patient. Several aspirations were performed and hooklets found, but the tumor increased, and as there seemed to be a danger of its bursting into the thorax, it was decided to incise and drain it. This was effected by making an incision in the eighth intercostal space, opening the pleural cavity. Air entered freely. On introducing his finger, Mr. Owen readily felt the diaphragm, which was bulging upward, but the lung was collapsed and could not be felt. The phrenic pleura was then incised, and with it the diaphragm. On passing the finger through the opening in the diaphragm the tense cyst was felt at once. From it a considerable amount of fluid was drawn by aspiration, so that some of its surface might be dragged through the opening in the diaphragm and up to the skin-wound. It was there fixed by four hare-lip pins, so that the phrenic and costal pleura might become glued together and the cyst be subsequently incised and drained without risk of leakage into the pleural space. On the fourth day the cyst was incised. Bile-stained fluid escaped, and pieces of cyst-wall which looked like rotten wash-leather. A large-flanged drainage-tube was inserted, and the cyst washed out daily with warm iodine water. Large pieces of cyst-wall came away. The patient made a complete recovery. The pneumo-thorax gradually disappeared, as also did a slight effusion of fluid into the pleural cavity. When seen by Dr. Broadbent a short time since, the patient was well and strong, and the lung had descended to its proper level.

On Monday last, at the Medical Society of London, Dr. Richardson, F.R.S., read a paper on what he termed "Pneumo-paresis." It was, he said, usually confounded with pneumonia, but there was no fever, and the disorder was preceded by a distinct chain of nervous symptoms. He described three typical cases. All three were in women, and all terminated fatally, in a few days from the onset of the disease, from asphyxia pure and simple. The physical signs were dulness, commencing usually in the bases of the lungs, but sometimes in patches, with fine crepitation at first, soon becoming moist, and in the later stages, bronchial râles. Treatment had proved useless. He had tried ergot, ammonia and nux vomica, and digitalis, in different cases, but the symptoms ran an unbroken course. Dr. Douglas Powell remarked that the cases looked like pneumonia without fever. Dr. Hughlings Jackson suggested that acute croupous pneumonia is a variety of herpes zoster. Dr. Routh said the cases which Dr. Richardson had described appeared to him to be the condition described in young persons as atelectasis pulmonis. Dr. Angel Money said he saw little reason why the cases should not be set down as cases of genuine croupous pneumonia. He objected to the title pulmonary paresis, because in any case it was not the lungs, but the vessels, that were paralyzed. The cases reminded him of what the French called "rheumatic œdema," occurring in the lungs.

Another eminent physician has just quitted our ranks—Sir George Burrows, Bart. Full of years and honors, he died on Monday last, in his eighty-seventh year.

(Those who contend that the pursuit of medicine is not favorable to the attainment of longevity will please note.) Sir George Burrows was one of the old school of physicians, and was educated at the University of Cambridge, where he distinguished himself not only as an oarsman, but also as a mathematician, graduating as tenth wrangler in 1825. He received his professional education at St. Bartholomew's Hospital, London, where he was a pupil of Abernethy, whose youngest daughter he subsequently married. After graduating in medicine at Cambridge he was appointed First Assistant-Physician at St. Bartholomew's Hospital. In due course he became Physician, an office from which he retired in 1863. In 1871 he became President of the Royal College of Physicians, and received his baronetcy three years later.

The Society of Apothecaries are petitioning the Privy Council in opposition to the Colleges of Physicians and Surgeons. The University of Cambridge is likely to do the same, so the royal colleges are likely to have a lively time of it.

OUR PARIS LETTER.

(From our Special Correspondent.)

MORE ABOUT ANTIPYRINE—TINEA DECALVANS A NERVOUS DISEASE.

PARIS, December 16, 1887.

AT the meeting of the Academy of Medicine, last week, Dr. A. Robin, the newly elected member, read a paper on the action of antipyrine on nutrition. The paper contained a continuation of the researches he had undertaken in 1885 and in 1886, and the following are the conclusions arrived at by the author: Antipyrine always diminishes the quantity of urine in healthy subjects. In typhoid fever this diminution is more marked than in the normal state. In chronic conditions the same is the case, and the diminution is the more considerable the more the nutrition is compromised. There is also a diminution of the quantity of urea. In the normal state antipyrine augments the secretion of lithic acid; it diminishes the quantity of the phosphates. In acute conditions it diminishes phosphoric acid, and also urea. The sulphuric acid of the sulphates is sensibly diminished, as is also the sulpho-conjugate acid. To sum up, antipyrine diminishes the quantity of urine, the solid materials, urea, the total nitrate, the relation of the nitrate of urea to the total nitrate, the chlorides, phosphoric acid, the sulphuric acid of the sulphates, and the sulpho-conjugate acid. It increases lithic acid, the relation of phosphoric acid to the nitrate of urea, phosphorus incompletely oxidized and its divers relations, sulphur incompletely oxidized and potash. These phenomena would place antipyrine among the medicamentous series which diminish the waste of tissue, and to which Professor Germain Sée has given the name of "médicaments d'épargne." The nitrate being eliminated in smaller quantity, this signifies that antipyrine diminishes the disintegration of the nitrate materials; it now remains to be seen what becomes of these materials in the economy. Antipyrine augments the excretion of the phosphorated materials, and of potash. This potash in excess cannot come from the muscles, nor from the red globules; it therefore appears rational to give it the nervous system as its origin. But at the end of two days this augmentation of the potash gives place to a diminution of its elimination at the same time, which augments the elimination of the phosphorus incompletely oxidized. Antipyrine acts, therefore, in slackening the nervous oxidations; it does not act in an equal manner on all the organs of the economy; it acts above all on the organs rich in nitrogeneous and in phosphorated materials. This would explain the election of antipyrine for the nervous system. Antipyrine produces a depression of the nervous activity; the anæsthetics which head the list of depressors of the nervous activity have a chemical action similar to that of antipyrine.

The deductions from these researches may be summarized as follows: 1. Antipyrine first acts on the nervous system, the excitability of which it moderates, not in a purely dynamical manner, but in acting on its elementary nutrition. 2. It diminishes the organic disintegration, and still more lowers the organic oxidations, whence the production of an excess relative to the lithic acid and of the nitrogeneous extractive materials, which are less soluble, and consequently with more difficulty eliminated than urea. It is probable that this influence on the general nutrition is the immediate consequence of the effects of antipyrine on the nervous system, as almost all depressing medicaments of the nervous activity act nearly in the same manner. 3. Antipyrine possesses also an antiseptic property very marked, even at a feeble dose, and which appears to be as manifest in the organism, and without any injury to it, as in the experiments of the laboratory. The author further observes that these three propositions indicate what should be the applications of antipyrine. It acts against pain, against painful cardiopathies and angina pectoris. As regards its administration in the treatment of fevers, Dr. Robin considers it very much compromised, as its beneficial action in these cases is very doubtful. Thus, for instance, while endeavoring to diminish disintegration, we must do everything to favor the oxidation of the disintegrated products, because the oxidations give birth to soluble residues. As antipyrine does not fulfil this indication, it should not be employed in this or any other fever. From these considerations, and from its special action on the element pain, Dr. Robin suggests that the substance now known by the name of antipyrine would be more correctly termed "analgesine," or "neurasthenine." Professor Verneuil observed that he had been rather successful in the treatment of surgical septicæmic fevers by antipyrine, which Dr. Robin, however, considers a corroboration of his conclusions respecting the therapeutic properties of this drug.

At the same meeting of the Academy Dr. Ollivier read a paper in which he endeavored to prove that "pelade," or tinea decalvans, was a non-contagious and non-parasitic malady, and that its origin was purely nervous. He therefore considered it inexpedient, and even cruel, to prevent pupils affected with the malady from attending their schools, and sometimes for a lengthened period, much to the detriment of their studies, and perhaps of their future career, particularly as even dermatologists are divided among themselves as to whether the malady is contagious or not. Professor Hardy, the well-known dermatologist, took up the subject, and stated that although he never discovered a parasite peculiar to the malady in question, yet from his vast experience he had every reason to believe that it was contagious, and this hypothesis was confirmed by the fact that since measures have been taken to exclude children so affected from schools the cases have become much less frequent in them. Dr. Cornil, the distinguished histologist, does not believe in the contagiousness of tinea decalvans in the majority of cases, for no one as yet has discovered either a mushroom or a micro-organism which may be looked upon as the peculiar agent of the disease. To this Dr. Hardy retorted that it does not follow that because no micro-organism was discovered in tinea decalvans it can be affirmed that this affection was not contagious, for although the microbe of measles and of scarlatina has not been seen, no one will contest the contagious nature of these maladies.

THE MEDICAL ACT FOR NEW YORK STATE.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: One of your correspondents, in a recent letter, signed "Medicus Erraticus," suggests the need of amending the recent medical act by prefixing the word "but" to the fourth section, so as to make it congruous with the third.

Your correspondent has been also mine, as he admits. He says, too, that he has corresponded with the Secretary of State in this matter. He concedes that both the Secretary of State and myself have advised him that there is no need of such an amendment, without which the statute is perfectly plain. Nevertheless, he seems to think the amendment should be made, because the clerk of an adjacent county has chosen to construe the law in such fashion as to absolutely distort the plain meaning of a provision more carefully examined by some of the best lawyers in the Legislature than any other in the act.

There is absolutely no need of this amendment, and it would be absurd to introduce a bill for the sole purpose of making it, although there are some other amendments by which the statute might be improved and made clearer.

The annoyance of your correspondent is very natural, and not to be wondered at, but I have already advised him that he can compel the county clerk by mandamus to obey the law. This, however, he may reasonably consider not worth the while. But, as a practical question, he is not likely to suffer any inconvenience, and if he should, the county clerk would be responsible for it in damages.

Under the law of 1880 the clerk of another adjoining county undertook in the same way to construe the law contrary to its clear intent, but his opinion, although ostensibly supported by that of two judges of the Supreme Court—not sitting as such, however—to whom he had not clearly presented the facts, was shown to be absurd in three cases where the courts were called upon to pass upon the question.

This is another such case, where it seems impossible to supply with an intelligent idea of the statute "a wise fellow; and, which is more, an officer; and one that knows the law—go to!"

Yours very truly,
W. A. Purrington,
Counsel New York County Medical Society.

Army and Navy News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from December 18 *to December* 31, 1887.

Biart, Victor, Captain and Assistant Surgeon. Relieved from further duty in Department of Dakota. S. O. 293, A. G. O., December 17, 1887.

Swift, Eugene L., First Lieutenant and Assistant Surgeon. Ordered for duty at Fort Spokam, Wash. Terr. S. O. 293, A. G. O., December 17, 1887.

Baxter, J. H., Colonel and Chief Medical Purveyor. Ordered to inspect the Medical Purveying Depôt at St. Louis, Mo. S. O. 296, A. G. O., December 23, 1887.

Banister, William B., First Lieutenant and Assistant Surgeon. Ordered to proceed to Fort Lowell, Ariz., and report to Commanding Officer for duty, upon the arrival of Surgeon P. J. A. Cleary, at Fort Wingate, N. M. S. O. 135, Department of Arizona, December 20, 1887.

Official List of Changes in the Medical Corps of the United States Navy for the week ending December 31, 1887.

Biddle, C., Passed Assistant Surgeon. Detached from the Marine Rendezvous, Philadelphia, and placed on waiting orders.

Cleborne, C. J., Medical Director. Detached as member of Medical Examining Board, December 31st, and ordered to Norfolk Naval Hospital, January 5, 1888.

Bradley, M., Medical Inspector. Detached from Naval Hospital, Norfolk, January 5, 1888, and placed on waiting orders.

Clark, J. H., Medical Inspector. Detached from special duty at Portsmouth, N. H., and ordered as member of Examining Board at Washington.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending December 31, 1887:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	5
Scarlet fever	139	16
Cerebro-spinal meningitis	2	0
Measles	42	9
Diphtheria	153	59
Small-pox	0	0
Yellow fever	0	0
Cholera	0	0

The Consumption of Alcohol on Mortality and Health.—Dr. Walter F. Morgan, of Leavenworth, Kan., referring to the observations of M. de Flaix, reported in a recent issue of The Medical Record, writes: "Allow me to call attention to what seems a very important omission of M. de Flaix in considering the effects of alcohol, viz., the influence of climate. It seems superfluous to call to mind the rule, to which there are few exceptions, that it has ever been in the coldest and dampest regions of the earth where most alcohol is used, and where most can be endured by mankind. Statistics should be handled with much circumspection when used to batter down an opposing dogma, otherwise they may, like the boomerang, belabor the hand that wields them. Still, the general fact will, I think, remain unshaken, that *climate* has much to do with the quantity of alcohol used, or that can be used, without great and manifest injury, among the civilized nations. The experience of the English in India sheds much light upon this point. There are other factors which M. de Flaix, in his ingenious *résumé*, has forgotten to consider; for instance, in comparing Italy with Spain. Among the causes which have produced the anomalous and unfortunate condition of the latter country, described in so graphic and masterly a way by Backle, he makes no mention of the use or non-use of alcohol as a cause of the degeneracy of that nation. I hope that the esteemed author will pursue these investigations still further, and inform us of the probable effect on the physical and moral condition of Italy; for example, should her inhabitants consume for the next fifty years as much alcohol *per capita* as is now consumed in Russia. If to the Italian's fiery climate and more fiery temper were added this extra amount of 'fire-water,' does it require a prophet to foretell the disastrous results? The degradation, the ruin, and the almost total extinction of our own aborigines, too surely point to alcohol as one of their chief causes to permit us to doubt. M. de Flaix does not take into his account how much the 'richest and most vigorous nations' may be indebted to the potent accidents of climate, soil, laws, religion, etc., as factors in their development."

The Provident Dispensary Plan in Germany.—Sickness insurance is meeting with some favor in Leipzig and other German cities. The law authorizing the operation of such companies permits the insurance to all classes of handworkers except clerks and salesmen, but these may be included by local authority. The action of this law is very noticeable in the tax for maintaining the sick poor, it being decreased 21,673 marks in Hamburg in one year. The total number insured under the law is 4,294,173, or 91.7 per 1,000 of the population.

ON SOME POINTS IN THE SURGERY OF THE URINARY ORGANS.[1]

By REGINALD HARRISON, F.R.C.S.,

SURGEON TO THE LIVERPOOL ROYAL INFIRMARY, AND LECTURER ON CLINICAL SURGERY IN THE VICTORIA UNIVERSITY.

Lecture I.

URINE FEVER AND TOXIC URINE—THE FORMATION OF STRICTURE TISSUE IN REFERENCE SPECIALLY TO THE TREATMENT OF URETHRAL STRICTURE.

Mr. President and Fellows: Let me, in the first place, thank you for permitting me to address your ancient and learned society in the capacity of Lettsomian Lecturer for the present session. At the same time, and with a full consciousness of my inability to approach you as I would desire, let me also ask your indulgence while I attempt to follow in the direction selected by many who, in preceding me in this chair, have so largely contributed to the practical advancement of medicine and surgery.

As I have already indicated, I propose making some observations relative to certain points arising out of the surgery of the urinary organs. It is now some years since my attention was directed to the circumstances under which fever was occasionally seen in connection with various lesions involving the urinary tract. It appeared to me that the subject had scarcely received the attention it deserved, and that a further knowledge of the etiology of what I would speak of as urine fever, as opposed to ordinary wound fever, might be of service to us as practical surgeons.

Let me, for the sake of clearness and comparison, briefly illustrate in a familiar way what I mean, and then I can the more easily deduce the points upon which I desire to lay stress this evening.

In surgical practice we have long been accustomed to recognize, after injuries and operations, a form of excitement which is generally known as wound or traumatic fever. It varies in degree according to circumstances, it is generally attended with some elevation of temperature, and it usually declines without proving either serious or fatal. Since the due recognition of those principles upon which Listerism is based, the development of this kind of fever has been considerably restricted, if not entirely abolished.

In striking contrast with this we have a distinctive form of fever, not unlike ague in many important respects, which is alone seen in lesions involving the urinary tract. Let us take, for example, the simple operation of internal urethrotomy. Here an incision, limited to a few lines in length, is made in the urethra, which the patient for some two or three hours is probably unconscious of. Then he is seized with a rigor, which terminates in fever and an elevation of temperature. As a rule, these symptoms decline in the course of a few hours, possibly to be repeated. More rarely the rigor and fever are followed by suppression of urine, convulsions, and speedy death, post-mortem examination failing to discover any reasonable or recognized explanation for these phenomena. These symptoms, though, as a rule, in only slight degree, more frequently follow internal urethrotomy, accidental wounds of the urethra, and the introduction of a catheter or a bougie. Even the last-mentioned operation, simple as it usually is, has proved fatal in the course of a few hours, with little or nothing to show in explanation. Here, then, as I have said before, we have a train of symptoms resembling ague, which are only called into existence in connection with lesions involving the urinary tract. In order that I may be perfectly understood as to the phenomena referred to, let me briefly illustrate the kind of case alluded to by narratives from my own practice.

Some years ago, in a case of extremely tight stricture, I performed an internal urethrotomy on a young and otherwise healthy male; three hours afterward he had a rigor, followed by high temperature, convulsions, and suppression of urine, and in forty-six hours he was dead. Post-mortem examination failed to prove anything except that the operation had been properly performed.

In the course of last year I saw a boy, eleven years of age, who, having ruptured his urethra by a fall, had retention of urine for thirty hours before I visited him in consultation. A catheter was passed with some difficulty along the lacerated canal and retained, the retention being in this way relieved. On the following morning he was visited, and found to have passed a restless night, with a temperature of 102° Fahr. About four o'clock the same day his usual medical attendant, Dr. Davies, was summoned, and found the patient in severe convulsions, and absolutely unconscious. The temperature was then 105° Fahr. He could not swallow; the fits recurred with much violence, attended with opishtotonos, and he became comatose and died at midnight; that is to say, about twenty-four hours after I first saw him and the catheter was passed.

I could not help observing that so long as this patient had retention he was comparatively safe; when, however, an opportunity was afforded to the urine of coming and continuing in contact with the laceration in the urethra by means of the retained catheter, then a process of acute poisoning seemed to commence, which speedily terminated in death.

In 1874 a healthy middle-aged man was under my care for a tight urethral stricture, for which, in the course of treatment preliminary to dilatation, a metal instrument carefully passed was followed by some very slight bleeding. Four hours after this he had a rigor, and his temperature went up to 103° Fahr.; this was followed by a succession of rigors, at intervals of from eight to twelve hours, with occasional vomitings. For over fifty hours the amount of urine excreted was only four ounces. During this period the pulse was quick and thready, the tongue dry and brown; there was a tendency to drowsiness, with occasional delirium, and death appeared to be imminent. After remaining in this serious condition for ten days he ultimately completely recovered, though he complained of muscular pains and much prostration for some time afterward.

Illustrations such as these, and others that I could quote, seemed to indicate that the presence of urine in a wound, under certain circumstances, was capable of generating an aguish form of pyrexia, which I shall speak of henceforth as urine fever. I am aware that some authorities are accustomed to speak of all the phenomena I have just illustrated under the one name of urethral fever. Such a term I think is misleading, inasmuch as it seems to connect the symptoms produced with the precise part, rather than with the process, for wherever throughout the urinary tract urine can be placed under certain conditions, there can all the phenomena usually associated with the term urethral fever be produced. With the view of endeavoring to throw some light on the causation of this, I determined, some years ago, to investigate (1) the relationship between urine and a wound which leads to the development of urine fever; and (2) the probable nature of the influence or material producing it.

---

[1] The Lettsomian Lectures, delivered before the Medical Society of London, January, 1888.

To the elucidation of these two important practical points I would now desire to direct your attention.

In the first place, it appeared to me that the development of urine fever might be traceable to the kind of contact that existed between a wound and the urine. I thought I would test it in the following way. Taking a number of cases of subpubic urethral stricture, which were unfitted for treatment by dilatation, I adopted the following procedure:

Internal urethrotomy having been performed, and all obstruction being removed, so that a full-sized grooved staff could be passed into the bladder, the patient was placed in the lithotomy position, and a median cystotomy was performed, quite independent of the previous internal operation, so as to admit a full-sized drainage-tube, such as I usually employ for this purpose, to be passed into the bladder. By this combination of internal and external urethrotomy I treated a considerable number of urethral strictures of the worst type, with results which time has already shown have been eminently satisfactory, both so far as the immediate comfort of the patient was concerned and the permanency of the relief that was afforded.

After a number of trials of this kind I soon found that as was my drainage so was my freedom from fever; urine fever only occurred where the former was imperfect. When urine, even in very small quantities, was pent up in a recent wound, fever resembling ague invariably followed. When, on the other hand, urine was allowed to escape freely and continuously, as after a lateral lithotomy, no such symptoms were developed. But, further than this, in connection with the operative treatment of stricture, it was observed with much uniformity that, in cases where it was impossible to obtain perfect urine drainage, the urine might, so to speak, be sterilized by local or general measures. This tended considerably to prevent the urine undergoing changes and yielding products which were calculated by their absorption to produce this special kind of fever. For instance, I found that, after an internal urethrotomy, certain antiseptic precautions, directed toward the wound as well as the bladder, for the purpose of acting upon the contents of the latter, considerably reduced both the frequency of these attacks as well as their severity. This was chiefly in connection with the use of solutions of corrosive sublimate for irrigating the wound, as well as for retaining within the bladder. Further, it was impossible not to recognize the importance of certain drugs which, by their elimination in some degree through the urine, seemed to render the latter less capable of exciting a specific fever where it remained in contact with a recent wound. This was most marked in the case of quinine, which is so largely eliminated by the urinary apparatus. In some cases of internal urethrotomy that were observed, the production or not of urine fever could be largely influenced by the administration of quinine. As bearing upon the sterilization of urine in connection with operative procedures on the urinary apparatus, I will refer to a passage from a recent writer who, in bearing testimony to the value of boracic acid as a prophylactic against urethral fever, states that in some forty urethrotomies he had had but one case of urethral fever, and that occurred in an instance where the precaution of sterilizing the urine by the administration of boracic acid had been accidentally omitted. The consequence of this was a violent chill on the third day after the operation, with a high temperature. These observations, then, taken collectively, seemed to me clearly to indicate that the kind of contact between fresh urine and a recently made wound was in itself sufficient to determine the occurrence of urine fever as a consequence.

I will now pass on to notice, in the second place, the probable nature of the influence or material by which the fever is actually produced.

During the last few years some important investigations have been made relative to the development of animal alkaloids, both in the dead and living, by Messrs. Gautier, Peter, and Bouchard in France, and by Drs. Lauder Brunton and A. M. Brown in this country. An address of much interest on this subject, in its relation to practical medicine, has also been recently delivered by Sir William Aitkin. To all these gentlemen we are indebted for much valuable information. From these investigations I do not think there can be any doubt in coming to the conclusion that the secretions of living beings are capable of forming leucomaines—alkaloid bodies having poisonous properties—and that many phenomena connected both with health and disease may thus be accounted for; "for," as Gautier remarks,[1] "of all the extractive composite residua, the alkaloids of animal origin are worthy of the deepest interest. It is only now that they have become familiar to us. They claim our special study from the fact of their constant presence in normal secretions, and must be classed with the most active agents known." From my observations in connection with the surgery of these parts, it seems probable that the development of urine fever is really due to the absorption of some such poisonous compound as an alkaloid which is derived either from urine, or tissue, or wound decomposition, or from all combined, and I would base this conclusion not from any chemical discovery that, so far as I know, has hitherto been made, but from the following deductions, which seem to be warrantable from what I have already stated:

1. That the presence of urine in relation with a recent wound is necessary for the production of what I have spoken of as urine fever.

2. That mere contact of urine with a wound is not sufficient for its production.

3. That the retention of fresh urine within the area of a recent wound is almost invariably followed by its development in a greater or lesser degree.

4. That where urine is placed under such circumstances as have been last mentioned, the liability to the development of urine fever is greatly diminished when it is sterilized by local or general means.

5. That the retention of fresh urine, blood, and the débris of damaged tissue in the confines of a recent wound for a certain time, at a temperature of somewhere about 100° Fahr., could hardly be possible without chemical changes taking place in the constituents referred to.

6. That there is a common origin for urine fever is rendered probable by the uniformity of the symptoms attending it, which, though differing in degree, are identical, whether following a surgical operation or an accidental wound.

As some may not be prepared to accept from me, though fortified with the reasons I have urged, that urine or urethral fever is the product of a definite poison introduced into the system, let me occupy your time for a few moments while I quote from the last essay[2] of one of the most original thinkers the medical world ever produced; I refer to the late Dr. Austin Flint, of New York.

"Analytical Chemistry," he observes, "carries investigation beyond the limits of microscopical observation.

---

[1] Professor Armand Gautier's Introduction to the Animal Alkaloids. By Dr. A. M. Brown.

[2] Medicine of the Future: Address written for the Annual Meeting of the British Medical Association, 1886.

The latter, at the present moment, both in pathology and physiology, seems to promise most; but is it not a rational anticipation to look for future results from chemical analysis of the components of the body, in health and disease, which in brilliancy and practical utility may surpass those of the labors in this field of investigation during the past half-century? The medical semi-centenarian can recall the enthusiasm aroused by the labors of Liebig. Histology is now in the ascendant, but it is safe to predict that before the lapse of another half-century there will be another era in organic chemistry, and that light will penetrate dark recesses which histology cannot reach. . . . The supreme objects of study in pathology at the present time are the discovery of micro-organisms and their natural history. But these agents, it is probable, are pathogenetic, not directly, but indirectly, by means of the toxical products of their activity. What are these products, and how do they give rise to the phenomena of disease? We may ask the same question of certain of the poisons introduced from without the body. How is it that fractional quantities of morphia, hyoscyamin, strychnia, aconitia, atropia, and other alkaloids produce their lethal effects? It conveys no adequate information to say that they act upon the nervous system. This is merely the statement of a fact, not an explanation. For the latter we must look to the organic chemistry of the future."

But objection may be raised against the views I am advocating relative to the way in which urine or urethral fever is developed by the fact that it sometimes arises under circumstances where it may be difficult to prove that any actual breach of surface in the urinary tract has been inflicted. For instance, as I have already said in illustration, some degree of urine fever frequently follows the passing of instruments along the urethra, as in the treatment of urethral stricture. It would not be difficult to illustrate every degree of this complication, from the most transient rigor with slight febrile excitement to the severest form of septic intoxication, rapidly terminating in death. And this leads me to speak of the influence of the epithelial lining of the urethra in making the canal water-tight, or, more correctly speaking, urine-tight. And out of this will necessarily arise some remarks on the pathology of urethral stricture and abscess with extravasation of urine. Let me take an illustration of what I mean by the protecting power of the epithelial lining. A patient with a stricture, I will say, has a catheter or bougie passed; this may be followed in the course of a short time with a rigor and some fever, and no further inconvenience is experienced. What has actually taken place is that the epithelial lining has been scraped off at one or more points, and this has permitted urine leakage and absorption to take place at the points injured. If further proof of this is required, take instances where prolonged attempts to pass catheters in cases of urethral stricture have been made and proved futile. Then, in consequence of the degree of retention, and as an alternative, an inspirator-needle is introduced above the pubes, and the urine is drawn off in this way without coming in contact, or remaining so, with any portion of the urethra which may have been wounded by the attempts made to give relief by catheterism. I have never known rigors or fever follow the relief of retention by supra-pubic aspiration, though the extent to which the urethra has been lacerated by attempts at catheterism has been considerable as well as sanguinary. There can be no other explanation for the absence of characteristic rigors and fever under these circumstances than the fact that urine has not been allowed to come and remain in contact with a freshly made wound. And in connection with this point I cannot help remarking that in the protecting power which the epithelial lining of the urinary apparatus exercises, we may probably have an explanation of certain phenomena which have been observed but not accounted for. Some have concluded that the bladder is capable of absorbing some of its contents, while others, on the contrary, not only have denied the possibility of such an inference being drawn, but have pointed out how serious might be the consequences if there was any liability to such a contingency. It seems that both of these conclusions may be true, and the explanation I would offer is that by injury to, or disease of, its epithelial coat, the bladder may be rendered capable of absorbing what it contains, to the detriment of the individual, as we see in those cases now often referred to by the name of catheter fever. In recognizing the power of the epithelium to prevent or permit absorption, I am in agreement with other observers, among whom I may mention Dr. London, of Carlsbad, who has made some investigations upon this point.[1] Further, it is important to notice that when a urine fistula is transformed into a permanent urine channel, as after Cock's operation, we find the passage becomes lined, like the urethra, with epithelium, and thus it acquires the power of transmitting urine without leakage. We could not have more positive evidence than this in support of the view that the epithelial coat is a necessary part of any canal which has to perform the function of transmitting urine.

Applying, however, these remarks to the pathology of urethral stricture, let us see how this is brought about, and how the protecting influence of the urethral epithelium may thus be demonstrated.

A stricture of the urethra is generally considered to be due to more or less prolonged inflammation of the lining membrane of the canal, which ultimately leads to the deposition of organized lymph in the peri-urethral tissues. This ultimately is converted into a dense connective tissue, which subsequently shows a remarkable tendency to become contractile. Thus the escape of urine from the bladder is interfered with by the degree to which these contractile masses prevent the expansion of the canal to anything like its normal extent. Now, all this may be very true on the whole, but it does not enter into details with which we should be acquainted for the prevention and treatment of the disorder.

It will be convenient to take an illustration for the purpose of tracing more gradually the process of stricture-making, as a consequence of a specific urethritis or gonorrhœa, which is generally admitted to be the common cause of the former affection. The acute form of the disorder, unless care is taken, is very apt to become merged into the condition commonly known as chronic granular urethritis. By the latter term we are to understand that at one or more spots within the urethra the epithelium has become so damaged, as a consequence of the prolonged inflammation, that it ceases to render the canal urine-tight, and a slow process of escape of some of the constituents of the urine into the tissues comprising the urethra and surrounding it, takes place. As a consequence of this and to prevent urine soaking further into the tissues, inflammatory exudation is excited, and barriers of lymph, which ultimately become organized, are thrown out opposite the places where the leakages take place. Thus splints of plastic tissue are formed, corresponding with the spot or spots where the epithelium has been so damaged by persisting inflammation as to cease to discharge its normal function. In this strengthening of the urethra we recognize, in the first instance, a conservative action; eventually, however, as in other compensating processes, certain inconveniences follow which constitute, as it were, an independent disease. In addition to the careful observations which have been made relative to the pathology of gleet, and the changes that are induced by chronic inflammation in the epithelial lining of the urethra, by Dr. Oberlaender,[2] of Dresden, there are other considerations which seem to indicate that an excessive form of plastic exudation in the tissues around the urethra is probably excited by the interstitial leakage or exosmosis of some of the constituents of the urine through the walls of the canal.

---

[1] Berlin. Klin. Wochen., No. 11, 1881.

[2] Vierteljahr: für Dermatologie und Syphilis. Wien, 1887.

Among those I would mention are: (1) That though the mucous membrane is the tissue chiefly involved in the primary inflammation, it is, as a rule, only secondarily implicated in the stricture-forming process. In many instances it will be found after death that the dimensions of the mucous membrane are not permanently altered, and that it is possible to split a stricture without necessarily damaging the lining membrane of the canal; (2) that the plastic exudation which makes up a stricture differs from other exudations provoked in other parts of the body by inflammation in the degree of its density and tendency to contract. There is no tissue I am acquainted with in the human body—except perhaps that found after scalds and burns, where the original tissues are entirely destroyed—which is so tenacious and resisting as that constituting the usual form of urethral stricture, nor do I know of any other canal or duct which, either as a consequence of injury or disease, is liable to be involved in such changes as a strictured urethra represents; (3) the character of the cicatrix which is formed in connection with ruptures and lacerations of the urethra unmistakably shows the effect produced in the healing process of a recent wound which is constantly submitted to the action of more or less pent-up urine. Here we have a cicatrix formed, which of all strictures is the most resisting and contractile. At the present time, when we are so much occupied in devising means for the radical cure of hernia, one cannot sometimes help thinking and wishing that it were possible to transplant the process of tissue-thickening and contraction, as observed in connection with the formation of traumatic urethral strictures, to the parts constituting the weak points we are desirous of consolidating in the abdominal parietes. Here it would be serviceable instead of being detrimental.

Further, the form in which stricture-tissue is deposited, and ultimately exercises contractile pressure on the urethral passage, is strongly suggestive that in the first instance it served the purpose of strengthening the wall of the canal, and thus preventing further leakage of some of the constituents of the urine taking place at points where the epithelial coat had been more or less permanently damaged. Most strictures are the result of organized lymph which has been deposited in the sub-mucous tissue in an irregular form. An annular stricture is comparatively rare, except when due to traumatic causes, such, for instance, as an injury to the whole calibre of the urethra.

It may, however, be urged that the view I am advocating is open to objection on the grounds that urine leakage is invariably followed by acute forms of inflammation, such as we see when extravasation has taken place. In reply to this I would say that, so far as I have been able to observe, the process of urine transition through the mucous membrane of the urethra, which has been deprived of the protecting influence of its epithelial lining, is extremely gradual, so far as the process is concerned, and does not necessarily imply that all the constituents of the urine are distributed among parts which are not adapted to receive them. Where a pathological process is slow, time is permitted for that adaptation which the human tissues are proved to be so capable of. But the exudation which a damaged epithelium may permit of does not necessarily imply that all the constituents of the tissue are thus brought into contact with tissue under circumstances where the most active and destructive forms of inflammatory mischief must inevitably be aroused. Some years ago I recorded the following case, which, at the time, seemed to me of much importance in reference to the subject now under consideration. It was as follows: The case was one of stricture, with extravasation of urine, occurring in a person suffering from Bright's disease of the kidneys. Though the extravasation had come on suddenly, and had existed for twenty-four hours unrelieved, there were no signs of acute inflammatory action and commencing gangrene, such as are usually expected. However, the tension being considerable, I incised the parts involved in the extravasation. As the fluid escaped from the incisions, I noticed that it had not that strong ammoniacal odor which is so perceptible in such cases. Subsequently I treated the stricture, which was exceedingly tight, and kept in abeyance the more threatening urinary symptoms. I was somewhat puzzled for an explanation, as I felt sure that the case was one of extravasation, and not acute scrotal œdema. How was it then that extravasation and confined urine failed to excite gangrene? I collected some of the urine as it trickled through the wounds and compared it with some subsequently drawn off by the catheter. I found them identical, and in both there was an almost complete absence of urea. This, then, to my mind solved the mystery, and explained that as there was no urea to decompose there was no source for the production of the ammonia by which the destruction of tissues in connection with extravasated urine is effected. By the absence of urea the urine was rendered chemically harmless to the tissues with which it came in contact. In the same way, and by a process of leakage, I apprehend may be explained some of those rare cases which have been described as scrotal or perineal urinary cysts, where a urinous fluid with little or no direct connection with the urethra is retained within a fairly well-developed envelope.

In illustration of the formation of stricture by urine leakage, due to epithelial desquamation or abrasion, I would point especially to those cases of multiple stricture caused by spots of induration in various parts of the canal. In a patient who was recently under my care, almost the whole length of the urethra was strictured by a series of nodular deposits, chiefly in relation with the floor of the canal. These could only be explained on the supposition that the urethra had almost entirely lost its normal power of conducting urine in the course of a long gleet, and that these numerous centres of induration and contraction marked the spot where leakage of some of the constituents of the urine had been permitted to take place. It will not be necessary for me to extend these views for the purpose of explaining certain facts observed in connection with peri-urethral abscess and extravasation of urine, which in practice we are all familiar with. What applies to the plastic form of exudation applies equally to the suppurative. In this way, however, is explained the fact that in these cases, when suppuration occurs and the matter is evacuated by incision from the perineum, the urethra is found passing through the abscess-cavity, completely isolated, and without showing any direct connection with the suppurating focus. It is under these circumstances that the unsupported canal occasionally gives way under the expulsive powers of micturition, and the urine is first forced into the abscess-cavity prepared to receive it, and subsequently among those tissues where it may be the more easily extravasated.

There are one or two practical points relative to the treatment of stricture and injuries of the urethra arising out of what I have thus ventured to bring under your notice to which I should like to refer before concluding. In the first place, the knowledge that certain relations between a wound and the urine may cause and keep up urine fever will prove of service to us in practice, as I will illustrate in the following way. Not long ago I treated a case of urethral stricture by Holt's method of rapid divulsion. Contrary to my usual experience of the operation, the patient had a severe rigor three hours afterward, and a temperature of 105° Fahr. On the following day this was repeated with, in addition, almost complete suppression of urine. As it appeared to me that the patient would die if he absorbed any more toxic material from the wound, I had him placed in the lithotomy position, and, passing a grooved staff, I performed a free median cystotomy, and put a drainage-tube into the bladder. I should add that there was nothing to indicate that suppuration had occurred; the time was too short for its development, the symptoms being clearly due to urine-poisoning. After this was done there was neither rigor nor fever, and urine was again rapidly excreted. By thus suddenly altering the relations of the wound with the urine the whole complexion of the case was immediately changed for the better, and the patient made a good recovery.

In the next place, a due recognition of the function of the epithelial lining of the urethra shows that there is a right and a wrong way in making use of dilatation in the treatment of strictures. I am sure that more good follows the daily introduction of a bougie which passes quite easily, than when a larger size is less frequently used, but where, in fact, the principle of the mechanical wedge is aimed at by the process. In this way rigors and other inconveniences associated with the treatment of stricture by bougies is avoided. I have made a large number of observations bearing upon this subject.

Thirdly, when a stricture has become, or is, so contractile and dense as to render dilatation out of the question, if not impossible, then, I believe, the open method of treatment is the safest and affords the best permanent results. In fact, excepting the earlier forms of stricture which are satisfactorily treated by dilatation, the open method has furnished the largest proportion of permanent cures that have come under my observation in the collecting and noting of many hundred cases of stricture taken indiscriminately. And, in reference to this point, I must take exception to a statement which is frequently made to the purport, "Once stricture, always stricture." I could furnish many examples following the open treatment which are quite at variance with such a conclusion. In order that I may not be misunderstood in using the word "cure," I mean that a contractile stricture necessitating the constant use of the bougie has been so influenced by what has been done as to render any further use of this instrument unnecessary, and that after a lapse of time of some years' duration the urethra can be proved both to be structurally and functionally normal. The majority of these cases have occurred where the perineum has been opened for stricture complicated with abscess and extravasation of urine. Here it by no means infrequently happens, if the artificial drainage made by the surgeon is free and direct, that a healthy scar, such as we see after lithotomy, takes the place of the dense contractile stricture which has sloughed by the acuteness of the inflammation that has been aroused. I should meet with no difficulty in fully illustrating this point. By the open treatment of stricture, of course, I mean the perineal section of Syme, or a modification of it, to meet some special circumstances, such as the double operation of external and internal urethrotomy combined, as I have already described. It must, however, be borne in mind that a perineal section is seldom resorted to until the urethra is largely impregnated, so to speak, with old cicatricial tissue of a contractile nature. Hence, although you may put into the urethra by your operation a longitudinal splice of good, sound tissue, such as fills up the wound made in lithotomy, and so bring up the canal to its normal dimensions, you do not succeed in removing the tissue which you have merely divided. This still remains behind to contract and to mar to some extent results which, under other conditions, would be obtained. Still, in spite of the impossibility of removing the cicatricial tissue by a mere section of it, the results of perineal section, so far as I have observed them in cases where dilatation was insufficient, have proved both safe and satisfactory. The conditions, however, which the operation must necessarily fulfil are complete division of the stricture and thorough urine drainage. The difference between the wound of a lateral lithotomy and a perineal section is only this, that in one case you operate upon sound textures, while in the other they have been rendered permanently and almost hopelessly contractile. Still, on the other hand, when the conditions I have mentioned are fulfilled, the cicatricial splice of sound tissue which perineal section introduces into a bad stricture often proves of the greatest and most permanent advantage in cases suited for this proceeding.

Fourthly, that in wounds of the urethra, made either accidentally or in the course of surgical operations, which, by the nature of circumstances, have to be treated without due regard for urine drainage, means should be more systematically taken to prevent the development of urine fever, as well as the formation of a dense contractile cicatrix. I found, after repeated trials, in the case of internal urethrotomies, that much might be done by irrigation, locally and through the agency of drugs which were largely eliminated by the urine in promoting these objects.

Lastly, we must remember that the prevention of stricture is within our scope. If, as I have urged, the dense cicatricial material which constitutes a stricture is the result of urine leakage occurring in the process of a chronic inflammatory affection by the interior of the canal in one instance, while in another it is brought about by the constant contact of the excretion with an internal wound, as in accidental rupture of the urethra, then the importance in one case of irrigation as a part of the treatment, and free urine drainage in the other, is at once evident.

It is, however, in connection with ruptures of the urethra, such as are caused by blows and falls on the perineum, where the canal is more or less lacerated, that we see exemplified the most disastrous effects of permitting a wound to heal subject to the irritation that constant contact with pent-up urine is capable of exercising. Fortunately, as a rule in these cases, retention of urine for a time averts the liability to acute septic intoxication, such as I have already illustrated in an earlier part of this lecture. Though the future of these cases, relative to the kind and degree of stricture that follows, is in some measure determined by the character of the injury inflicted upon the urethra; whether, for instance, the canal is entirely torn across, or partially, either obliquely, longitudinally, or transversely, I have not the least doubt, from a careful observation of a considerable number of these cases, that those do best which are treated by perineal section and drainage without reference to the question of extravasation. When a catheter can be passed under these circumstances, and there is no evidence of urinary extravasation, it is often, I admit, very tempting to be content with this procedure, and to wait until there are further indications as to the necessity for incision. Such a course is almost invariably followed by the formation of a stricture of the most dense and contractile nature. Where incision is practised, as in those instances where there is evidence of extravasation, and the laceration proves to be only of a partial nature, the wound heals with a scar which shows but little tendency to subsequent contraction. In these cases we have remarkable illustrations of the damage that the presence of urine under certain circumstances is capable of exerting while the process of repair in a wound is going on. And what applies to the healing of wounds inflicted accidentally upon the urethra internally applies equally to others similarly inflicted on the canal for surgical purposes. I have elsewhere stated that for many years past I have taken some pains in collecting and noting cases of urethral strictures with the view of estimating the permanency or otherwise of the treatment to which the patient may have been previously submitted by various surgeons. The testimony that I have thus gathered from the examination of many hundred cases is certainly not favorable either to the permanency or the character of the relief that internal urethrotomy usually affords. Among the worst cases of stricture that I have thus met with have been those which have been treated by an internal section. If there is any force in the observations I have brought before the society this evening, I do not think there should be any difficulty in explaining how this happens, and of recognizing the importance of applying to the treatment of wounds of all kinds involving the urethra those principles which are the basis of Listerism—namely, drainage and cleanliness. There is no part of the human body to which disregard of these conditions is more likely to be attended with disastrous consequences, whether we have regard to the present or to the future. In conclusion, gentlemen, most speakers commence their discourse with a text; I prefer concluding with one: Urine can spoil tissue as well as blood.

ON THE IMMEDIATE APPLICATION OF THE PLASTER-OF-PARIS SPLINT IN THE TREATMENT OF CLUB-FOOT.

By PROF. GEORGE E. POST, M.D.,

BEIRUT, SYRIA.

WHILE many surgeons use plaster of Paris during the treatment of club-foot, I believe that it is usual, after the tenotomy, to postpone the application of the plaster of Paris for at least a week, often much longer. On asking surgeons the reason for this delay, the writer has been told that it was to avoid risk of swelling, and to allow ready access to the wound in case of necessity. An experience of fifteen years in its use, and a large number of cases, have satisfied him that with proper care the plaster may be used from the first, with considerable shortening of the time of treatment, and no risk to the patient.

The wound caused by tenotomy of the tendo Achillis or of the plantar fascia, with thorough antiseptic precautions, will heal by the first intention, if measures be taken to keep in coaptation the whole track of the incisions, plus the gap made by stretching the parts in the effort to restore the foot and ankle to their normal positions. This is best accomplished by a pad of aseptic or medicated cotton wool, which makes soft and even, but most effective, pressure, and prevents a vacuum into which air can be sucked or in which blood can be pocketed. The wounds so treated unite readily and as quickly as any other wounds in the deeper parts. As there is no swelling of a wound which heals by the first intention, there is no reason from this cause why a plaster bandage may not be at once applied.

Swelling is most apt to occur from pressure over the metacarpo-phalangal joints of the great and little toes and the dorsum of the foot just anterior to the ankle, and the inner aspect of the tibia just above the internal malleolus. Care in padding with cotton wool these places, where the strain from the bandage is felt, will prevent undue pressure and the œdema which is sure to result from it.

Of course, swelling will result from too forcible torsion of the foot, and undue straining of the ligaments of the complicated tarsal and tarso-metatarsal joints. Experience and the tactus eruditus alone can inform the surgeon correctly of the amount of strain to put upon these tissues at the first dressing. But it is safe to say that the existence of the tenotomy wounds, if properly treated, does not increase the risk of the first torsion of the foot. It is furthermore true that a considerable amount of stretching, or even laceration, of these ligamentous tissues will be borne with inconsiderable swelling, or with swelling at points little pressed by the bandage and plaster, and that a plaster splint, which has been properly padded at the points where bony prominences are thinly covered by skin, will seldom have to be removed because of œdema of the foot.

The practice of the author is as follows:

The foot and leg, as far as the knee, are thoroughly cleansed with soap and water, and rendered antiseptic by sponging with a three per cent. solution of carbolic acid. The hands of the surgeons and assistants, and all the instruments and accessories, are carbolized. The necessary tenotomies are done in the usual manner, but while the instrument is doing its work a wad of aseptic cotton wool is pressed over the surroundings of the wound in such manner as to press the skin and subjacent tissues into the hollow formed by the separation of the cut subcutaneous tissues, at once arresting hemorrhage, and bringing about immediate coaptation of the whole of the divided tissues. If more than one tenotomy is necessary, an assistant carefully holds the cotton pad over one wound while the other is being made.

Supposing the deformity to be in the right foot, the patient is laid on his back, with the affected leg projecting from the knee beyond the edge of the table. An assistant grasps the calf just below the knee, and holds it firmly to the edge of the table, managing the thumb and forefinger of his hand so as to form a ring at right angles to the axis of the limb, and allow of the application of the bandage as high up as possible. The surgeon, sitting at the side of the table, with the left hand everts and flexes the foot so as to overcome as far as possible the deformity, and applies an absorbent aseptic bandage beginning at the inner border of the foot, crossing the sole outward, and surrounding the metatarsus twice. Between the first and second turns of the bandage a pad of cotton wool is placed along the outer border of the metatarsus and first phalanx of the little toe, overlapping a little the sole and dorsum, and a similar one along the metatarsus and first phalanx of the great toe. A pad of cotton wool is then laid over the instep, and then a turn of the bandage carried from the outer edge of the foot, across the pad and instep, to the inner aspect of the tibia above the malleolus, which is also protected by a pad of cotton wool. The bandage is then carried once or twice around the leg, so as to cover the wound and make equable pressure on the pad over it, and then carried from the outer aspect of the leg obliquely over the dorsum to the inner aspect of the foot, and by repeated figure-of-eight turns around the foot and lower part of the leg, with suitable reverses, the whole, including the heel, is covered. The roller is then carried up to the upper part of the leg and pinned or sewed. During all this process the surgeon's left hand has maintained the foot in the desired position, a point of no little importance, to prevent the movement of the wounds, which will cause oozing of blood and introduction of air. As the left hand can render but inefficient aid in the passing of the roller, it is very desirable to have a clever assistant, who will pass and repass it to the right hand of the surgeon. The right hand of the assistant who holds the leg will be the best for this purpose. I lay considerable stress on the surgeon's retaining the manipulation of the foot, that he may judge of the exact position that it is to assume. The co-operation of the two hands of one man is always more perfect than that of two persons.

A plaster bandage about two inches broad, and four to six yards long according to the size of the limb, previously well soaked in water, is now to be neatly applied, but never stretched on, and whatever pressure is made in redressing the position of the foot should be by the left hand of the surgeon, never by pulling the plaster bandage. Both the original roller and the plaster bandage should simply retain what is gained. If necessary a second bandage may be applied, and then the surface covered with a thick cream of plaster. If the bandages have been skilfully applied, the foot will give very little when the left hand of the surgeon is taken off.

The second phalanx of the great toe, and the third of the other toes, should be left out. It is very important that no crowding of the metatarso-phalangal joints should result. The natural line of the toes should be preserved.

The child should be kept on the table, and prevented from moving the leg until the plaster has hardened. The mother or nurse should carry the child, with the leg held up, and not allowed to dangle, for three days, or until time has been given for the healing of the wounds, and to be sure that there is no swelling.

If the child is old enough to walk, and the deformity has been sufficiently overcome to bring the sole of the foot nearly into position, he may be allowed to begin to use his foot after three days. If, however, the deformity is only partially overcome, or there is a little swelling of the toes, it is well to wait until another splint has been applied, which may be after a week or ten days, according to the judgment of the surgeon.

Two to four applications of a plaster splint are usually enough to bring about a cure in children under five, who have not very bad club-feet calling for resection of the tarsus, or who have not large callosities from long walking on the dorsum of the foot or on its outer edge.

TWO CASES OF RAYNAUD'S DISEASE, WITH REMARKS.[1]

By R. VAN SANTVOORD, M.D.,

NEW YORK.

My first case was that of a young man, whose family history presented nothing noteworthy except that apoplexy was common in the branch of the family which he resembled in physique. He himself, prior to the development of his Raynaud's disease, had always been healthy, though not remarkably robust. He had never had any severe disease. He was not neurotic; had been subject to chilblains in boyhood, and suffered from frost-bitten auricles on a short exposure on a very cold windy day. The disease never went beyond the "dead-finger" stage. When about eighteen years old, being then a student in college, he used to suffer from "dead fingers" from time to time if he studied in a room a little below a comfortable temperature. The attacks amounted to only a trifling inconvenience, no discomfort being felt beyond a slight prickling on return of the circulation. The attacks ceased to occur later on, possibly owing to more robust physical development, and have never recurred. Since that time he has had marantic thrombus, with embolic pneumonia, when run down in general health, owing to a combination of depressing influences, but is now, at the age of about thirty-four years, in robust health. There has been no return of the "dead fingers" since his college days.

My second case, a woman, came under my observation when she was fifty years of age. Apoplexy on her mother's side was the only morbid condition which was prominent in her family history. The patient herself has suffered from malarial fever from time to time for years. She had some kind of fever, of short duration, in childbed, nineteen years ago. She has suffered always from occasional sick headache, and regards herself as "nervous." She was always thin up to six years ago. After that she gained flesh until six months ago. Since then she has been loosing flesh and strength, and suffering considerably from dull headache, the only apparent cause for which was some defects in the plumbing in the house into which she moved at the beginning of her recent trouble. For the last thirty years she has suffered from "dead fingers." The right forefinger was the first to be affected. The trouble has become gradually worse, until now, at times, all the fingers are affected. She suffers also from cold feet, and the toes present the same waxy pallor that the fingers do. The pallor never extends above the fingers. Slight chilling on putting the hands in cold water, or handling ice, brings on an attack even in warm weather. During the attack the fingers are cold, numb, and somewhat stiff. Circulation is easily restored by using the hands, or plunging them in warm water. No unpleasant sensation, beyond a slight tingling on the return of the circulation, is experienced. Until the development about to be described, the matter had not amounted to more than a trifling inconvenience. In addition to the finger phenomena the patient occasionally had numb feelings in her lower extremities, particularly in the left thigh, above the knee, and tingling in the arm and leg. I was called to see the patient on November 4, 1887. She had been suffering from an onychia of the right ring-finger, which had almost healed, and which did not present any unusual features. The right forefinger presented a slight break in the cuticle, along the outer edge of the nail, the skin being swollen and tender at this point. The end of the finger was numb and white, the nail blue. There was slight aching of the finger, but no great amount of pain. In the course of a few days some drops of pus came out from alongside of the nail. The whole finger became slightly swollen and painful, but no deep phlegmonous process developed. It soon became evident that the whole thickness of the skin, on the anterior surface of the finger, from the middle of the first phalanx to the tip, was entirely necrotic, together with the underlying pulp. She had not noticed any unusual frequency of attack of syncope in the affected finger. In fact, her attention was being directed almost entirely to the ring-finger, the numbness and whiteness of the part of the forefinger, which afterward became necrotic, being little regarded. The sensation of fingers and toes, except the necrotic portion, seemed perfect both for touch and temperature.

The skin of the finger was slightly dry and rough, a condition which she says exists all over her body. Sphygmographic tracings of the radial arteries showed a pulse the same on both sides, of normal tension, and showed also that the vessels were of normal elasticity. Physical examination of the heart was negative. The urine was normal, containing neither albumen nor sugar. From the time that I explained to her the probable connection between the necrosis of the end of the phalanx and the "dead-finger" phenomenon, she was able to avoid the recurrence of the latter for days at a time by avoiding its exciting cause.

The first of these cases is of a type which is probably not very uncommon. It may escape observation from the fact that it so little inconveniences the patient that attention is not called to it. It is of interest to recall this. Dieulafoy[1] states that it is a very frequent symptom in all forms and all stages of Bright's disease. The second case is remarkable because the malady had never reached the stage of local asphyxia spoken of by Raynaud as intermediate between that of local syncope or pallor and gangrene, but gangrene developed after a very slight inflammatory trouble. The absence of the burning and tearing pains, which also are said to be present before the gangrene shows itself, was also remarkable. It may be objected that in this case an inflammatory trouble preceded the gangrene. This, however, was limited to the side of the nail, not more than eight or ten drops of pus ever collected, and the necrosis of the skin extended over almost the whole width of the end of the phalanx. The gangrene may therefore, I think, fairly be associated with the local syncope.

The recent literature of Raynaud's disease has made some important additions to our knowledge.

Pitres and Vaillard,[2] in 1884, obtained autopsies on two cases. The first case was that of a female, twenty-four years of age, who had always been stupid, and whose mind became very much impaired toward the last. Tremor, and finally contractures, preventing walking, occurred in the lower limbs. There was also tremor on voluntary motion. Passive motion of the legs was possible only within very narrow limits, and was very painful. Both feet became first blue, cold, anæsthetic, and finally gangrenous a few weeks before death. Neither sugar nor albumen was found in the urine. Late in the disease sloughs occurred over the glutei and on several spots of the body. Autopsy showed internal hydrocephalus, and an old affection of the cerebral pia mater. The internal organs, including the heart and blood-vessels, showed no abnormality, except slight fatty change in the liver. The microscope showed the spinal ganglia to be normal, slight sclerosis of the dorso-lumbar region of the cord, and more or less extensive inflammatory changes in the peripheral nerves of the gangrenous parts. The second case was that of a fifty-six-year-old rag-picker, who had no hereditary taint, and was always healthy until final illness. For four months she had a peculiar anæsthesia of the soles of her feet, without motor disturbance. Both soles then became blistered after a long walk. Later, both feet became swollen and tender, then blue, anæsthetic, ecchymotic, and finally gangrenous. The patient was suffering from a very severe diarrhœa during the development of her severe local symptoms. The autopsy showed normal brain, cord, lungs, liver, kidneys, and heart. The aorta was slightly atheromatous, but both veins and arteries coming from the feet were normal. Neuritis of the nerves of the affected parts was found.

---

These cases were controlled by the examination of the nerves in a case of senile gangrene, in which the nerve-structure was found normal, even in the gangrenous parts.

The authors conclude: 1st, That cases of symmetrical gangrene are often seen in the extremities which cannot be explained by any cause heretofore recognized, such as heart- and vessel-disease, ergotism, septic infection, etc.

2d. In such cases, above the mortified parts, in an extent of from twenty to thirty ctm., exist profound alterations of the peripheral nerves, which show the histological character of a parenchymatous neuritis.

3d. The nerve-disease appears not to be caused by the mortification, for it is not found in gangrene caused by vessel changes. It is probable that the neuritis causes the gangrene.

4th. In addition to the usual forms of spontaneous gangrene a neurotic gangrene must be classified, which, in its development and symptomatology, is to be likened to other trophic diseases, which occur after inflammation of peripheral nerves.

A third case of symmetrical gangrene, accompanied by neuritis, was presented by Wigglesworth[1] to the London Pathological Society early in the current year. Almost equally instructive is the clinical case of Weiss.[2] This case suffered from neuralgic pains in anus, attended after a while by "dead fingers" and superficial sloughs on finger-tips. In course of the disease the patient suffered from swelling of finger-joints and of the left knee and elbow. The finger-nails became misshapen. Sloughs occurred implicating the left side of the nose, several phalanges, the nates, and the left cheek. Paræsthesia of temperature-sense, delayed sensory conduction, and a symptom-complex resembling progressive muscular atrophy developed in the arms. Atrophy of the left cheek, and a typical paralysis of the left cervical sympathetic also occurred. The striking points for our present purpose, in this case, are the facts that gangrene occurred in the fingers, where there was cyanosis; in the buttocks, where there was no obvious vaso-motor disturbance; and in the left cheek, in which the vessels were largely dilated in consequence of the paralysis of the sympathetic. Weiss argues that the vascular contraction in the fingers was not the cause of the gangrene, because gangrene occurred also in parts of the body where there was no evidence of vascular contraction, or where there was even marked vascular dilatation. He therefore regarded the gangrene as trophic, a view strengthened in his case by the other trophic disturbances. He assumed that the morbid condition was in the posterior columns of the spinal cord. His observation was published, however, three years before the above quoted autopsies. As strengthening his position, it should also be noted that in Pitres' two cases there is no history of paroxysmal local syncope or asphyxia.

Other clinical cases might be quoted in which there were marked indications of peripheral neuritis.[1] In Raynaud's own description of symmetrical gangrene,[2] the severity of the burning, tearing pain, radiating through the whole limb, is emphasized. Pitres calls attention also to the gangrene which has followed certain cases of direct injury to nerves.[3]

As an offset to this mass of evidence pointing to peripheral neuritis as the probable cause of symmetrical gangrene, and its frequent preliminary symptoms of local syncope and asphyxia, may be cited two cases of Raynaud[4] in which dimness of vision, accompanied by manifest contraction of the retinal arteries, occurred, in one case alternately, in the other simultaneously, with attacks of local asphyxia in the hands. These cases Raynaud thought spoke decisively for a central location of the disease. Two[5] cases in which paroxysmal hæmaturia occurred seem to point in the same direction.

A review of all this evidence seems to me to suggest that the phenomena of local syncope and asphyxia, while due undoubtedly in the first case to arterial spasm, and in the second either to arterial spasm with venous reflex (Raynaud), or to spasm of the venous radicals (Weiss), may have lesions differing in character and possibly in site in different cases.

The symptom-complex in which these phenomena occur differs very much in different cases. It is not to be denied that a very close association exists between the vascular spasm and the gangrene. This was especially prominent in my own second case, in which, beyond occasional slight numb feelings and tingling in the extremities, there was only the "dead-finger" phenomena and the gangrene; there was none of the great pain often described, and no other symptoms of nervous derangement, unless the dryness and slight roughness of the skin could be so regarded. It is also worthy of note that the patient did not notice any pallor of the affected skin, except at the necrotic portion, during the development of the gangrene, and for days avoided any appearance of the local syncope by avoiding exposure to cold.

The conclusions which I draw from the evidence which I have thus briefly brought before you are:

1. That local syncope and asphyxia may possibly occur as symptoms of more than one morbid condition.

2. That symmetrical gangrene is to be regarded as a tropho-neurosis, in which peripheral neuritis is the only lesion yet demonstrated.

3. That while the close association between vascular spasm and symmetrical gangrene is not to be denied, the two phenomena are to be regarded rather as results of a common cause than as cause and effect.

With regard to treatment, the recommendation of the constant current to the spine, or locally, made originally by Raynaud, has been sustained by some other observers.[6] Good results obtained in other cases may be summed up by stating that they seem to have resulted from the successful treatment of concomitant disorders.[7] In my own second case I attempted nothing more than a general tonic treatment, the result of which is not yet decided.

106 West 122d Street.

Note.—In discussing this paper, Dr. M. Allen Starr mentioned a case of his own of typical Reynaud's disease, upon which electricity had no appreciable effect whatever.

A CASE OF COMPLETE ADHESION OF THE SOFT PALATE TO THE PHARYNX, WITH AN OPERATION FOR ITS CURE.

By E. HARRISON GRIFFIN, M.D.,

ATTENDING SURGEON OF THROAT AND NOSE DEPARTMENT OF BELLEVUE HOSPITAL OUT-DOOR POOR, NEW YORK.

Patient S——, aged forty-four; occupation, seaman; a native of France, applied to me November 29, 1883, complaining of shortness of breath. He wanted to know if anything could be done to restore his speech. He was able to utter a sound, but he could not turn this sound into words.

He had contracted syphilis twenty years previous; he was married, and his wife had miscarried three times. One child was born living, and is now twelve years of age, and is apparently in fair health.

This communication was made on paper, as the patient was unable to talk.

His nose was entirely eaten away down to the nasal bones, so that all that remained was a small opening in the face. The nasal fossa would fill up with large green crusts, which he dislodged with a hair-pin every morning and evening. The stench from these crusts was exceedingly offensive. I took out two, which were fully two and a half inches in length and shell-like in form.

The patient's mouth was so closed up by syphilitic adhesions that I could pass in my two fingers only, with great difficulty, by stretching the mouth to its utmost capacity.

A laryngoscopic view or a complete view of the throat at this stage was impossible. The first operation I undertook was enlargement of the mouth, which was done by means of a knife. Afterward little wooden stretchers, or gags, were inserted, to prevent the wounded surfaces from growing together again.

After this was accomplished I found that the uvula and the lower part of the soft palate were entirely destroyed, and the remaining part of the palate was firmly adherent to the pharynx, so that the upper pharynx was completely separated from the lower pharynx.

The complete occlusion of the two pharynges is extremely rare. I have met with it in only three cases. It is by no means rare in tertiary syphilis of the throat to find a partial adhesion of the parts; but it is extremely rare to find a complete adhesion. Often a small opening can be discovered, sometimes only large enough to admit a small probe, but still large enough to admit a small current of air.

In this case I covered the lower pharynx with iodoform and filled the nasal fossa with water. My iodoform was not moistened. I now determined to liberate the palate from the pharynx, so that I could give my patient nasal breathing, and also give the nasal cavity an outlet into the throat. I first passed a silver probe down through the nose to the pharynx, and with a tenotomy knife cut where the palate bellied. After I had thoroughly separated the palate from its attachment, with no little difficulty, the parts were sprayed with a solution of tannin. No anæsthetic of any kind was used.

I now began to pass the largest sound I could obtain through the opening into the upper pharynx. I afterward had a sound made after the following description: The body of the instrument was about two inches in length and was blunt-pointed at the end, and gradually widened as it reached the base; it was somewhat similar to a triangle in shape. The base was an inch and a half in width. To the broad end of the instrument was attached a long handle, so that it could be manipulated in the throat. I found that with this instrument I could keep the opening the required size, and prevent it from closing.

Had the wound not been treated with sounds after cutting, the opening would have filled up in a very short time. This is a peculiar characteristic of syphilitic tissue, where we seek to enlarge an opening, whether it be in the pharynx or nasal fossa.

In a case of nasal stenosis, now under observation, I have seen the parts close completely after opening the nasal canal three times, every time giving the patient complete breathing space, taking out at each operation a large piece of cartilage at the point of union. In a short time the parts were firmly adherent again.

The parts in this operation healed nicely, and within four days absolutely no pain was felt from the passage of the instrument. An examination of the larynx showed complete paralysis of the abductors of the vocal cords, and the whole mucous membrane lining the larynx was in a state of hyperæmia; this accounted for his loss of voice.

At the beginning of my operations I had placed my patient under iodide of potassium, but I was compelled to give him one hundred grains, three times a day, before I could produce any effect. I do not consider this an unusually large dose in cases of tertiary syphilis of the throat or nose, and have often given larger doses and maintained them during a longer time. This was given in water; his stomach stood it nicely, and I kept this amount of iodide up for two weeks, when the amount was gradually reduced. Later I gave him only tonic doses.

Within a month and a half from the time of the first operation on the mouth, the patient had entirely regained his voice, and had increased something like fifteen pounds in weight. His voice was now quite clear and strong. I had an artificial nose made by Tiemann & Co., which supplied his missing member very well. I gave him one of the sounds above described, and told him to use it once or twice a week for a year.

I often hear from him, and he reports the breathing through his artificial member excellent, and his voice good.

The Physical Condition of the Masses Improving.—In an article published in the *Fortnightly Review*, Mr. Charles Roberts deals with the question of the physical degeneracy of our town populations. The inquiry is chiefly concerned with the condition of the laboring classes, though, in contrasting variations of death-rate, average-weight, stature, and the like, there is an inseparable reference to the vital state of whole communities, without regard to rank (*The Lancet*). The author of this paper is not one of those prophets of evil in whose eyes the future of our poorer townsfolk wears only an aspect of unbroken gloom. It is true he does not ignore the fact that causes hostile to the natural and vigorous development of human life are more largely present in cities than in rural districts; but while admitting this, he justly objects to the wholesale acceptance of evidence derived from statistics which are still necessarily imperfect, and he acknowledges the certain past and probable future success of efforts in the direction of sanitary reform. The food question, though probably incapable of a wholly satisfactory solution, occupies a position much advanced beyond that which it held in the earlier half of the present century. The influence of this and other allied matters of nearly equal moment, a decided and general rise in wages, diminished cost of clothing, of house-rental, and of living as a whole, have, according to Mr. Roberts, exercised a most beneficial effect in checking that process of retrograde change which many regard, not without a reason, as a possibility of the future. Thus far, however, we feel a certain satisfaction that the evil of decadence is more visionary than real; but, at the same time, we must recognize the practical truth that continued future prosperity is compatible only with a vigilant observance of those laws of healthy life which nature constantly defends by imposing on those who disregard them the penalties of physical enfeeblement and final extinction.

Clinical Department.

A CASE OF RESECTION OF THE FEMUR FOR UNUNITED FRACTURE, WITH SOME POINTS OF INTEREST.

By C. C. JACOBS, M.D.,

FROSTBURG, MD.

On February 1, 1887, a patient, aged thirty, sustained a compound fracture of the lower third of the femur. The limb was treated in a wire suspension- and extension-splint until April 22d, when the case came into the writer's hands. The limb was placed in a plaster-of-Paris spica, extending from the toes to the perinæum, in which dressing it was kept till June 2, 1887, when there was found to be no union. On this date, assisted by my partner, Dr. Dorsey P. Fitch, and Drs. Price, Mason, and Getty, I performed resection in the following manner:

The patient having been anæsthetized, and the part to be operated upon prepared in the usual way for an antiseptic operation, an incision nine inches long was made on the outer aspect of the thigh, beginning at the knee-joint. The sharp end of the upper fragment, which had thrown out no callus, was found just under the integument, having perforated the vastus externus and cruræus at the time of injury. These muscles were divided, and by means of the chain-saw about one and three-quarters inch of the bone removed, which allowed of its easy reduction. The next step was to find and elevate the lower fragment, which was strongly flexed by the action of the gastrocnemius in pushing the popliteal vessels to one side. This fragment had thrown out some callus, which was pared off with a strong knife; then a hole was drilled in the end of the bone with a surgical engine, and a silver wire, threaded through the hole, served as a bridle, by means of which the bone was easily elevated into juxtaposition with the upper fragment, which was also drilled, and the two pieces of bone were firmly bound together with silver-wire sutures. The superior external articular was the only vessel ligated, but there was free oozing from the sawed end of the bone and surrounding tissues, which were very vascular. The wire was cut off short. Without waiting for the oozing to stop, the wound was closed with superficial silk and deep catgut sutures. A Levis' metallic patella splint was placed under the limb, and secured by a spica bandage, and the patient was put to bed. Next day the dressings and bed were saturated with blood, but the hemorrhage had stopped. Clean dressings were applied by Dr. Fitch, and the wound was not again exposed until the sixth day, when it was found perfectly healed throughout, without the formation of a single drop of pus.

The patient was seen every day, and at no time did his temperature go above 99° F.

The result was in every way satisfactory, and the patient has a firm femur, with about two inches of shortening.

The points of interest in this case relate, first, to the feasibility of the operation; secondly, to the safety of closing so large a wound before oozing has stopped; and thirdly, to the method of securing the bones in apposition.

First, as to the feasibility of the operation:

In consulting the text-books on the subject of resection of the femur, I was confronted with a melancholy array of statistics. Of 175 cases of resection of the femur, for gunshot injury, tabulated by Drs. Otis and Huntington, no less than 116 proved fatal, a percentage of 69.4. But we have a right to expect better results in civil practice.

In the "International Encyclopædia of Surgery," on the subject of resection of the femur, Ashhurst says: "Resection may be performed for the relief of ununited fracture, but in this part of the body is both a doubtful and a dangerous remedy; and should milder means fail to secure a union, the patient will, as a rule, do well to be satisfied with the adoption of some mechanical means of support, such as that devised by Professor H. H. Smith, of Philadelphia, rather than undergo the risks of a resection."

Fortunately, the above-quoted statistics and opinion were written before the days of antiseptic surgery as practised at the present time. I wish to say in this connection that this operation was performed under the strictest antiseptic precautions, and the wound was known to be absolutely aseptic when it was closed; and I believe that if, in such cases, in a healthy subject, the operation is performed in a strictly antiseptic manner, and the bones firmly sutured, the wound cannot go wrong, and the bones must unite.

Secondly, as to the safety of closing so large a wound before oozing has stopped:

This is a point of much interest to the rural surgeon, who often has to go to the country to operate, necessitating absence from his office for several hours, in many instances for a whole day. By closing the wound, as in the above instance, many hours of valuable time can often be saved.

Whether or not the blood thus imprisoned becomes absorbed, or enters into the new formation of bone, it is not the object of this paper to discuss; but the point that interests the practical surgeon is, whether or not such a wound can be sealed up and left so for days with safety to the patient. I believe, if the wound is perfectly aseptic, that it is absolutely safe; and a number of cases could be cited from my own experience that would verify the statement. There is one case, in particular, worthy of mention, as touching this point—it is the case of a shoulder-joint amputation for malignant disease of the humerus, in which the flaps were extremely vascular, eighteen arteries being ligated, but general oozing continued. The wound was closed and antiseptic dressings applied. The patient was seen every day. On the eighth day the wound was examined for the first time, and found to be perfectly healed, with not a drop of pus to be seen. This patient never had a temperature above 98.5° F.

Thirdly, as to the method of securing the bones in apposition:

I claim no originality in the method of this operation, it being, I believe, the way in which the operation is usually performed; but it may be of interest to compare it with the operation of Dr. Lemoyne, as described by him in a very interesting paper on the subject, read before the International Medical Congress at Washington, the following synopsis of which was published in THE MEDICAL RECORD of September 17, 1887:

"The bones were cut down upon, and the ends found to be overlapping nearly three inches. The ends were sawed off, the upper fragment in the form of a wedge; from the lower one a wedge-shaped piece of bone was removed, so that the upper fragment fitted into it. A hole was drilled in both bones about an inch and a half from the fractured ends. A stiff, flat, steel bar, with a prong at both ends, was placed lengthwise on the surface of the bone, so that the prongs were inserted into the holes; a stout piece of wire was then passed around the clamp and femur at both ends, and twisted close up, holding the clamp in position. The wires and clamp remained there nine weeks, when the wound was reopened and the clamp removed. The bone was firmly united, but the limb is two and one-half inches shorter."

The result in this case seems to be all that could be desired, but the points of objection are, first, it involves the sacrifice of an unnecessary amount of bone; secondly, it necessitates a second operation, at a time when, if the bones had been secured by wire sutures, and, if need be, by a splint, the patient ought to be cured and ready to leave his room. In this connection the attention of the profession is called to the question as to whether the wire sutures should be left long and brought out at the wound, and the latter kept open until the bone becomes united, and be then removed, or whether they should be cut short and allowed to become embedded in the callus, as was done in the case now reported.

It is now more than six months since this operation was performed. The man is walking on his leg, and there is not the slightest indication of irritation from the sutures or other causes.

ANTIPYRINE IN NEURALGIC HEADACHE.

Dr. R. R. Ball, Assistant Surgeon, U. S. Army, of Fort Riley, Kan., reports the following case: "A few days ago I had occasion to use antipyrine in the case of Miss K. F——, a young lady who, for several years, has been subject to violent neuralgic headaches. She had never gotten relief from anything she had tried. I gave her ten grains of antipyrine, directing her, if pain continued, to repeat this dose in half an hour. Fortunately for me, idiosyncrasy stepped in to prevent my directions being obeyed. In about five minutes after taking the ten grains she turned deathly pale, experiencing complete loss of strength, with violent palpitation of the heart and slight nausea. She immediately took to the bed, and summoned a physician. A few minutes later a peculiar and intense itching and burning of the fauces, of the conjunctiva, and of the lining membrane of the nose and middle ear occurred, making her feel, as she expressed it, that if she could scratch the inner membrane of her throat out she would be relieved. This condition was rapidly followed by intense burning and itching of the skin on the upper portion of the body, running on into fully developed urticaria. No emetics were used, as some time had elapsed before she was seen, half an ounce of brandy had been given, and in about two hours, with perfect rest in bed, the untoward symptoms passed off. In this case, as in many others, the headache was completely relieved—though I had never met such idiosyncrasy before. I can only account for the symptoms on the supposition of an idiosyncrasy, which is strengthened by the fact, as I learn, that her mother has been so affected by other things. She is also unable to eat strawberries and some other fruits. Perhaps it would be well if we always inquired more fully into the peculiarities of families. Certainly, I shall, in future, regarding antipyrine."

Antipyrine in Obstetric Practice.—Dr. Charles Milne, of this city, writes: "Referring to the letter of Dr. Hays, in a recent issue of The Medical Record, on the use of antipyrine and antifebrine as hypnotics, permit me to say that I have been in the habit of using the former for the past six months, not only as a soporific but as an anodyne, and I now use it almost exclusively, instead of opium or its alkaloids, to relieve pain and produce sleep, chiefly for the reason that it produces refreshing sleep, and alleviates suffering without producing any unpleasant after-effects. I find it especially useful in cases of wakefulness due to over-fatigue, or exhaustion following cases of protracted labor. It is also, I find, an excellent remedy for after-pains. I usually give it in doses of fifteen to twenty grains, and repeat in two hours if necessary, but the first dose nearly always produces the desired result. My experience with antifebrine has been too limited to enable me to express any opinion as to its merits in similar cases."

Leyden's Crystals without Asthma.—Dr. Pfuhl reports in the *Militärärztliche Zeitschrift* a case of a soldier suffering from a severe chronic bronchitis, in whose sputum Leyden's crystals were found in great numbers. The patient had not the slightest suspicion of asthma, but the sputum had the peculiar odor of spermatic fluid, which is said to be always noticed when Leyden's crystals are present.

Progress of Medical Science.

Gravity as an Expectorant.—It is claimed that in cases of pneumonia where there is great embarrassment of breathing from accumulation of secretion in the bronchial tubes, great benefit may often be derived by inverting the patient and having him cough violently while in this position. It is easily accomplished by a strong assistant standing on the patient's bed, seizing the sick man's ankles, turning him with his face downward, and then lifting his feet four or five feet above the level of the mattress. If the patient, with his face over the edge of the bed and his legs thus held aloft, will cough vigorously two or three times, he will get rid of much expectoration that exhaustive efforts at coughing failed to dislodge when not thus aided by gravity. Life has been saved by repeated performances of this manœuvre in pneumonia accompanied with great cyanosis due to inundation of the bronchial tubes with mucous secretion. It, of course, will have no effect on the exudate in the vesicles. Gravity is of value in a similar way in emptying the lungs of mucus during etherization.—*Polyclinic.*

The Treatment of Poisoned Wounds.—Dr. A. de Noé Walker has addressed a letter to *The British Medical Journal* in which he expresses the opinion that if Burnett's fluid, diluted with one-third of water, is at once poured on the abraded surface of penetrating wounds, whether inflicted by a venomous spider, hornet, scorpion, cobra, rattlesnake, or rabid dog, the patient may consider himself safe. The poisons of various venomous animals, however, differ widely in composition. Those of the spider, hornet, and scorpion are as yet not thoroughly investigated; but that of the cobra, along with other ophidians, is of proteid nature. That of the rabid dog is—at least recent researches would prove it so—of microbic origin, and bears no comparison with the others. It is not to be supposed that the same treatment is applicable to all. Alkaline lotions are usually the best for the venomous insects; we know of no antidote for snake-poison when it has once entered the system, and Burnett's fluid or chloride of zinc will not act any better than simple washing the wound with water. The antidote to rabies is probably not to be found in any chemical application. "Reducing" or "decomposing" agents can be found for all the poisons of chemical nature, but if the venom is at all intense, for example, snake-poison, the unfortunate part of it is that the amount of antidote requisite to neutralize or destroy the poison would be sufficient to destroy every tissue in the body it came in contact with, and thus, though a poison may be quite easily neutralized in the laboratory (for example, snake-poison by permanganate of potash), it cannot be effected when it has entered the system. Immediate washing of a poisoned wound under a tap of water will effect more than any application of Burnett's or other fluid. As to cobra-poison, when once a lethal dose has entered the circulation, no antidote or treatment will save the patient.

The Action of the Alkaloids of Veratrum.—Our knowledge of the action of the alkaloids of veratrum has hitherto been gained solely from the observations made with the amorphous substance veratrine, a body in reality not simple, but a compound of two bases, entirely differing in their properties. Lissauer has therefore deemed it advisable to repeat these observations with the perfectly pure crystalline substance veratrine. The results obtained in warm-blooded animals he sums up as follows: 1. Vasomotor paralysis, probably of central origin, although perhaps due in part to the direct action of the alkaloid on the muscular fibres of the small arterioles. 2. Slowing of the heart's action, usually only slight—occasionally, although only temporarily, very marked; the result being unaccompanied by any weakening of the heart's action when moderate doses are given.

3. Disturbance in respiration; slowing, with finally complete cessation, and death. 4. Disturbances in connection with the alimentary system; in the case of rabbits, salivation; in other mammals, in addition, vomiting and diarrhœa. 5. With large doses, convulsions of cerebral origin. 6. Changes in temperature, probably of secondary origin, and dependent on the vaso-motor disturbance.—*The Practitioner.*

Litholopaxy in Male Children.—Dr. Walsham believes (*The British Medical Journal*) that if proper precautions be taken, litholopaxy will be found as simple and as safe in children as it is in adults. As regards the performance of the operation, the same rules apply to both classes of patients. But the following points are, according to him, worthy of special notice: 1. That the lithotrite should be fully fenestrated, and the female blade well bevelled, so that no detritus may be retained between the blades, and the risk of nipping the mucous membrane of the bladder may be avoided. 2. That the evacuating catheter should be furnished with an accurately fitting stylet, in order that any fragment fixed in the eye may be displaced before the catheter is withdrawn. 3. That the meatus should be incised, and no force used in passing either the lithotrite or the evacuating catheter. 4. That the stone should be very thoroughly crushed, as the small size of the evacuating catheter will only allow the removal of small fragments. 5. That every particle of stone should be removed at one sitting. 6. That the first crushing should be as thorough as possible, so as not to necessitate the frequent passage of the lithotrite and evacuator. 7. That a small aspirator should be employed, to avoid any risk of over-distention or rupture of the bladder.

The Lesions of Morphomania.—Dr. Ball, at a meeting of the Paris Academy of Medicine, spoke on the subject of the lesions observed in persons addicted to the excessive use of morphine. The topic was suggested to him by the case of a woman who entered his service at St. Anne voluntarily, in order to get cured of the habit of taking morphine. She took daily about sixteen grains. At first immediate suppression of the drug was ordered, but the patient fell into such a state of collapse that a more moderate and progressive treatment was adopted. Sleeplessness and agitation were combated by enemata of bromide of potassium and chloral. Four grains daily of sparteine had to be given for the heart. The treatment lasted forty-two days, and, at the end of that period, the woman seemed to have quite recovered. But when about to leave the hospital she died suddenly. The autopsy revealed fatty degeneration of almost all the internal organs, especially of the heart, and the presence of morphine in the nervous centres.

The Physiological and Therapeutical Actions of Solanin.—According to Clarus, solanin is a narcotic poison which has the property of paralyzing the spinal cord and vagus endings, and of exciting the peripheric nerves (*The Therapeutic Gazette*, December 15, 1887). In former years Geneuil experimented with the drug, and came to the conclusion that solanin exerted its narcotic properties on the medulla oblongata, spinal cord, and nerve-branches, and thereby caused a paralysis of the extremities and of the sensitive and motoric nerves. Capparoni has recently conducted a series of experiments with solanin on man. His results are as follows: A very small dose of solanin (1.54 grain) will cause (especially in individuals with a sensitive stomach) a sensation of burning in the stomach, salivation, and nausea. All these symptoms prove that the drug causes a local irritation. When the drug is given where the stomach has been previously anæsthetized, or when it is administered hypodermically, this irritation does not take place. The same dose causes a lessening of the pulse's frequency and of the respirations, and a decrease of the reflex activity of the excito-motor tendency of the spinal cord and medulla oblongata. Solanin does not seem to have any influence on the brain-centres; it is not a hypnotic; the pupils do not undergo any change. In the circulatory system small doses of solanin lessen the rapidity of the heart's action and increase the pressure of blood in the arteries. Toxic doses, however, cause the pulse to increase greatly, and lessen the arterial pressure, and also increase the respirations. Solanin is thrown off by the kidneys, but has no effect on the secretion of urine, neither is it a diaphoretic. As to its therapeutical action, the author has found it of great value in cases where it was necessary to reduce the irritability of the spinal cord; also in asthma, in difficulties in walking, and muscular spasms of a peripheric origin, in tremor, etc. The author usually gave 0.15 to 0.30 gram ($2\frac{1}{3}$ to $4\frac{3}{5}$ grains) daily, divided into a lesser or greater number of doses, according to the special needs of the case.

The Relation of Tea-drinking to Nervous Disorders.—A paper on this subject, from the pen of Dr. W. N. Bullard, appears in the "Medical Communications of the Massachusetts Medical Society." The author has reached the following conclusions: 1. Chronic tea-poisoning produces a condition of irritability or hyperexcitability of the nervous system, and does this both directly by the action of the tea upon the nervous system, and indirectly by the production of gastric derangement. 2. Tea, taken frequently and in moderate doses for a considerable period of time, tends therefore to place the nervous system in a condition in which it is more easily affected injuriously by slight external influences. It therefore favors the production of many forms of functional neuroses, and, if such neuroses already exist, aids in their continuance. 3. There is no evidence that tea taken in the manner described causes any organic nervous lesion, but it is probable that if such nervous lesion should exist, tea thus taken might tend to cause an aggravation and continuance of certain symptoms. 4. There is no evidence that chronic tea-poisoning produces unaided any serious functional neuroses in persons not in any way specially predisposed thereto. It does, however, in the manner above described, act as an important factor in the production of neuralgia, hysteria, and allied affections. 5. When taken constantly in very large doses, dyspeptic symptoms usually intervene before irreparable harm is done to the nervous system. 6. In hemicrania, and possibly some other functional neuroses, there is probably a craving on the part of the nervous system for a slight stimulation, which is better afforded by tea than by any other equally accessible article, and for this reason patients with hemicrania are so frequently tea-drinkers.

The Elimination of Uric Acid by the Skin, and the Difficulty of Detecting Minute Quantities of that Acid.—Dr. Tichborne has made a study of this subject, the results of which he published in the *British Medical Journal.* He says that Dr. Garrod denied to the skin the power of eliminating uric acid. But the fact that the skin acts in this way has been demonstrated. Dr. Tichborne, continuing, says, concerning the murexide test, that from the description given in text-books one would imagine that nothing could be more simple in its application, and nothing more striking than the phenomenon produced, and when dealing with ponderable quantities of the acid it probably is so, but if we are seeking for minute quantities in a complex mixture, it is quite the reverse. The tests are *bien prononcés* with coarse quantities, but treacherous when dealing with traces. The three essentials which are requisite to the development of the murexide or purpurate of potassium test are the following: 1. The proportion of nitric acid to the uric acid present should never be in excess; it will be at once perceived that this presents a great difficulty when dealing with an unknown trace. 2. The amount of dilution requisite for the development is of considerable importance. 3. That there is no reducing substance present capable of reacting on the nitric acid. This is what he terms interference. All the following substances, which, unfortunately, are more or less mixed up with the secretions, interfere with the murexide test —lactic and sarcolactic acids, albumen, and sugar. He points out the necessity of separating these from the uric-acid residue before testing for that substance. Calculating that we are dealing with a saturated solution of uric acid in the cold, namely, one containing 1-15000th, it will be found that five parts of ten per cent. diluted nitric acid to twenty of the uric-acid solution is as much as can be used, while five to thirty is a better proportion. In practice, however, it is impossible to hit this off, and thus the numerous failures in detecting uric acid when it is present. However, he has adopted a plan of extreme simplicity, which, like a great number of simple arrangements, makes all the difference between success and failure. It consists in adding the ten per cent. nitric acid in a definite proportion as near as we could infer would represent the relative quantities given above, and evaporating the mixture in a water-bath at 100° C., without moving or stirring. Again, this evaporation must be performed in a very concave watch-glass. These two last precautions are the essential parts of the test; under exactly similar proportions it will be seen that, on trying it upon the ordinary flat glass, no results are obtained. But on the concave glass, the partially oxidized uric acid is gradually deposited upon the surface in what we may view as rings, which are concentrating as they go on. The remaining liquid is also gradually concentrating in acidity, until at some stage of the evaporation a circle is deposited just of the right concentration and relative proportion to form the murexide. The result in nine cases out of ten is the production of a halo of color, the edges of the glass and the centre being colorless. The edges represent the part where the substances are not sufficiently concentrated to react. The colorless centre represents the condition where the nitric acid has become too concentrated. If the uric acid is present in considerable quantities, a central circle of color is produced. The author obtained marked indications of uric acid in sweat collected by Dr. Meldon at the Turkish baths, by operating in the following manner: The perspiration was rapidly evaporated to a small bulk, and while warm, passed through a small filter. It was then acidulated by a few drops of hydrochloric acid, and allowed to stand some days. Traces of uric acid require time to be thoroughly deposited. The whole was then thrown upon a filter, and, when thoroughly drained, the filter was moistened with a few drops of alcohol, and then washed thoroughly with ether. The uric acid is insoluble in ether, while the lactic acid, etc., are washed away. This enables the murexide test to indicate the uric acid if applied in the manner given above.

CHLORIDE OF METHYLENE WITH THE ACTUAL CAUTERY.—M. Bailly, who is a great partisan of the actual cautery in different local affections, such as hydrarthrosis, incipient tuberculosis, and certain scrofulous affections, gave an account, before the Société de Thérapeutique, of the methods he has tried to render the operation painless. Ice with marine salt gave but little relief, and cocaine, with or without carbolic acid, gave also unsatisfactory results. Not so, however, is the case of the spray of chloride of methylene, which deadens all the sensitiveness of the derm in from two to four seconds. As soon as the skin whitens the operation can begin.—*Medical Press.*

NAPHTHOL AS AN ANTISEPTIC MEDICAMENT.—Bouchard has communicated to the French Academy of Sciences the results of a series of researches, from which it appears that naphthol, one of the derivatives of naphthaline, is an excellent antiseptic, surpassing even iodoform. Kaposi, several years ago, called attention to the value of this agent in the treatment of certain diseases of the skin, and particularly of scabies. He employs naphthol in a ten per cent. alcoholic solution, or in the form of ointment, and says that one or two applications will cure the most inveterate cases of common itch. For this purpose an ointment may be made with one part of naphthol and ten of vaseline. He has had equal success with naphthol in psoriasis, eczema, and ichthyosis, and there is nothing better, he says, to allay the tormenting itching of prurigo. Hensinger also speaks in high praise of naphthol as an external agent (alcoholic lotion or pomade) in the skin diseases mentioned above, in lupus erythematosus and in chancres. Under its use sores of a phagedenic character rapidly take on a healthy action. Van Harlingen, moreover, has seen favorable results from naphthol in obstinate cutaneous affections. The experiments to which allusion has been made have led Bouchard to regard naphthol as one of the best and safest of antiseptics. According to these a three per cent. solution markedly retards the development of the typhoid bacillus, as well as that of the bacillus tuberculosis. The same solution is fatal to the microbes of several of the parasitic diseases of animals, and prevents fermentations. Bouchard gives naphthol internally in typhoid fever, and believes that, if it does not abort this disease, it certainly renders its course milder. He regards a dose of forty-five grains a day as realizing the conditions of intestinal antisepsis, and affirms that in such doses there is no antiseptic agent which is more innocuous. This use of naphthol in typhoid fever has been followed to some extent in this country, with apparently favorable results. —*The Boston Medical and Surgical Journal*, November 17, 1887.

TREATMENT OF THORACIC ANEURISM BY THE INTRODUCTION OF WIRE.—M. Charmeil, of Lyons, has collected the details of fifteen cases of aortic aneurism, in which "Moore's method," as he terms it, was employed, from the original case in the Middlesex Hospital to three previously unpublished cases in the practice of M. Lépine (*The Lancet*, December 3, 1887). Although not one of the fifteen cases has resulted in the cure of the aneurism, M. Charmeil concludes that the practice itself does not involve any direct danger to the patient, and that the results ascertained at the necropsies have been encouraging. Clinically the treatment has nearly always been followed by local improvement, as well as by relief of subjective symptoms. He therefore thinks the method is justifiable and worthy of continued trial, and indicates as essential to its favorable practice a preliminary exploration of the aneurism by means of acupuncture needles, the use of the watch-spring of Bacelli introduced through a flattened cannula, and the most rigid adoption of antiseptic precautions. At the same time recourse should be had to Tufnell's dietetic treatment.

HYDROCHLORIC ACID IN GASTRIC JUICE.—A satisfactory reaction for hydrochloric acid in gastric juice appears still to be an unsupplied want. M. Ewald has brought forward a new reagent for the detection of free hydrochloric acid. It is composed of one part of vaniline, two parts of flucoglycine, and thirty of alcohol. On warming slowly the liquid to which the reagent is added, there appears a beautiful crimson-red color if the liquid contains hydrochloric acid in not less proportion than .05 gramme per litre. Lactic acid does not give this reaction.—*The Lancet*, December 3, 1887.

DANGER IN UNCOOKED MILK.—According to *The Lancet* milk epidemics of typhoid fever, scarlet fever, and diphtheria have repeatedly shown how severely the incidence of the disease has been felt upon those using uncooked milk. It has been shown that the cow may suffer from a disease which at present is rarely, if ever, regarded as of any importance by dairymen, and which may give to the milk a power of producing scarlet fever in those who consume it in its raw state.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 14, 1888.

IMAGINARY ULCERS OF THE TONGUE.

AT a meeting of the Paris Academy of Medicine, held on September 27th, M. Verneuil related some cases of imaginary ulcers of tongue. He had seen but five cases, and thought the condition was a rare one. The affection was characterized by acute pain in a circumscribed portion of the tongue, at the junction of the posterior with the middle third of the organ, at about the situation of the last lenticular papilla. The patients always believed that there was an ulcer at this point, and most of them thought that there was cancer of the organ. The movements of the tongue were free, though sometimes painful. Careful examination revealed absolutely no lesion. All the patients were between thirty-five and fifty years of age and were robust, with, seemingly, a rheumatic tendency. Various modes of treatment had been tried, but none of them had produced any amelioration.

In the discussion that followed the reading of this paper, several of the members stated that they had met with similar cases in their practice, and although the books were silent on the subject, the delusion referred to would seem not to be of very special rarity.

In the *Bulletin Médicale* for October 9, 1887, Dr. Poyet contributes an article on the same subject, in which he also takes the view that the affection is by no means so rare as might be supposed. The delusion, he says, may almost always be referred to one of four causes. In the first class of cases, to which those reported by M. Verneuil belonged, there is a neuralgia of the tongue, and the pain leads the sufferers to believe that ulceration exists. In the second class are patients who have read or heard of some person afflicted with cancer, and have been led thereby to examine their own tongues. They notice, perhaps, a somewhat prominent papilla, and their fears lead them to the conclusion that it is the edge of an ulcer or a commencing cancer. Others are hypochondriacs pure and simple, and are so convinced that there is an ulcer present that no amount of argument or demonstration can convince them of their error. Finally, certain patients with lingual psoriasis discover the white patch on their tongue and think that ulceration is present. When there is simply an enlarged papilla, the patient may make applications of one kind or another in the hope of curing the supposed growth, and the result will be pain, which serves only to confirm him in his delusion.

The treatment of these patients is in large measure a moral one. The patient's confidence must be gained, and he must be persuaded to abandon his delusion. When neuralgia is present much relief may sometimes be obtained by applications of cocaine or aconite. In the case of a hypochondriac, M. Poyet advises the use of the actual cautery or of some other painful application, for its moral effect. But, in any case, the cure of imaginary ulceration of the tongue, as of other imaginary diseases, is often most difficult, and at times impossible.

ELECTRICITY AND EMBRYONAL DEVELOPMENT.

SOME interesting experiments, which may possibly contain the germ of a valuable discovery in embryology, have recently been made by Dr. Giuseppe Fasola. These experiments, as related in the *Archivio per le Scienze Mediche*, vol. xi., No. 4, 1887, consisted in the passage of a weak induced current through frogs' eggs with a view to determine the effect of electricity upon the development of the embryo. The experiments were apparently conducted with great care, and every precaution wss taken to exclude all sources of error. The method of procedure was briefly as follows :

Several couples of strong and healthy frogs were taken and placed each in a separate compartment, and there kept until the deposition of the eggs was complete. The mass of eggs was then divided as nearly as possible into from four to six equal parts, some of which were submitted to the electrical currents, and others were kept under the same conditions, but without electricity, in order to serve for comparison. The conditions as to the size of the vessels, the temperature of the water, the amount of light received, etc., were the same in all the cases. The length of time that the eggs were exposed to the induced current varied in different experiments from one to sixty minutes. In some cases only one application of the electricity was made ; in others three or four in as many successive days. The ages of the eggs at the time the current was passed through them also varied from one to six days.

The first movements of the larvæ, as well as their complete liberation, took place in the eggs which had been submitted to the action of the electricity from twelve to thirty-six hours before they did in the other eggs which had not been so treated. In these eggs, however, there was a large proportion of failures. In many of them there was an early arrest of development, probably at the time of the application of the electricity, but in the greater number the larvæ were formed, but had failed to reach maturity. Possibly, as the author intimates, this was due to weakness resulting from the too rapid development of the ovum.

As to the mode of action of the electricity in thus accelerating the development of these frogs' eggs, Dr. Fasola suggests three hypotheses. It is possible, he says, that the action of the currents upon the mucin enveloping the eggs may have produced sufficient heat to effect this result ; or the elective affinities of certain of the chemical elements may have been so increased as to render their reciprocal action more prompt ; or, finally, the electricity may have promoted the particular molecular arrangements which are supposed to be concerned in the production of vital phenomena. In whatever way brought about, however, the acceleration did take place, and the results of his experiments, the author thinks, serve to render more probable the hypothesis that electricity and magnetism have a very important function in the most intimate and delicate of vital processes.

EPIDEMIC WINTER ITCH.

Dr. E. A. Neely, of Memphis, Tenn., states (*Mississippi Valley Medical Monthly*) that for the past three winters there has existed in Memphis and vicinity an affection of the skin which, from its great prevalence, might be considered epidemic. It begins usually in October, and lasts until spring. It is characterized by distressing itching, burning, and smarting sensations. The skin presents no lesion whatever, except that it is universally dry, harsh, and furfuraceous. The symptoms are worse at night, or on exposure to heat, and they increase and diminish with the fall or rise of the temperature. The favorite localities are the extensor surfaces of the thighs and legs, arms and forearms. It rarely attacks the body, and never the face, scalp, feet, or hands. It attacks persons of all ages, and is equally frequent among males and females. The majority of the sufferers appear to possess excellent health. It is not apparently contagious; nor, according to Dr. Neely, can it be traced to the presence of a parasite.

It is not identical with the so called "Michigan itch," but is probably the same affection as that described by Dr. Duhring, in 1874, as "pruritus hiemalis." This latter disease was described as having a predilection for the inner surface of the thighs, the popliteal spaces, and the calves.

It is generally stated that the disease is not due to any constitutional condition, and is not influenced by internal treatment. Defective action and nutrition of the skin, owing to the cold, is believed to constitute the basis of its pathology.

Dr. Tilbury Fox, however, states, and we believe correctly, that in many cases there is a gouty condition, or, at least, a deficiency in the excretion of nitrogeneous matters and bile products. It is to be regretted that some careful examinations bearing upon this point were not made by Dr. Neely. It is plain that there must be some other element than simply the action of the cold, for otherwise we cannot account for the fact that, among persons equally exposed, some suffer and others do not.

Treatment is not very effectual. The use of vaseline, with alkaline baths and carbolic acid, is most efficacious.

A NEW MICROBE OF SYPHILIS.

Syphilis is not transferable to lower species, with the exception, perhaps, of the ape, which animal Klebs and Martineau and Hammonic claim to have successfully inoculated. Despite this, there come from Japan reports that a new micro-organism has been found in the blood of syphilitics, that this has been cultivated, and that lower animals have been successfully inoculated. The disease resulting is not claimed to be identical with human syphilis, but it bears a very close relation to it. Hereditary syphilis, so called, was also produced, as shown by examination of the placental and of the fetal offspring of inoculated animals.

Dr. Disse and Mr. K. Takaki, Professors of Anatomy in the Tokio University, are gentlemen who claim paternity to the new microbe.

According to *The Lancet*, they examined chiefly the blood of syphilitic persons, especially of such as had been cured of all manifestations of the disease. They selected the skin of the face, on account of its great vascularity, of course cleaning it very carefully with antiseptics before making the necessary puncture. In most of the cases spherical bodies, nearly 0.001 mm. in diameter, which could be stained by Gram's method, were found; these occurred singly or in groups between the blood-corpuscles. They were not easy to be distinguished unless the layer of blood was extremely thin. A magnifying power of three hundred and fifty diameters was used, an oil-immersion lens and a good illumination being indispensable. They were, the writers believe, invested with an envelope. In non-syphilitic subjects, whose blood was examined with similar precautions, these bodies could not be found. From blood containing these organisms cultures were prepared, various media being employed. Of the cultures attempted about three-fourths were successful. Of course, extraneous organisms made their appearance, but with care pure cultures were obtained. When they were examined microscopically, there were found: 1. Simple spherical forms, having a diameter of 0.0008 mm. 2. Double spheres, looking like short rods with rounded ends; the length of these was 0.0018, and the breadth rather less than half the length. 3. Chains and groups really formed of the double spheres. 4. Occasionally three spheres in line, measuring 0.0027 mm. All these forms were invested with envelopes which did not take the stain, and therefore were difficult to distinguish. In one culture an ovoid bacterium, with a clear spot in the centre, was found on the third day, but subsequently this had apparently changed into the ordinary form.

From a study of the report of Dr. Disse and his associate, one concludes that they have made a thorough and careful bacteriological study, but that their claim to have found a specific microbe is not established.

THE NATURAL INSTINCTS IN EDUCATED WOMEN.

There has been running through the recent issues of the *Medical and Surgical Reporter* a curious and not altogether savory controversy as to the comparative intensity of the sexual feeling in men and women. Some of the correspondents were medical women, and presumably had specially good opportunities for obtaining physiological data. The general tenor of the statements made was in conformity with the prevailing view, that the sexual feelings are less active in women, and that the wife is sometimes injured by the excessive sensuality of the husband. Some striking illustrations of the reverse were, however, alleged to occur.

In the New York *Medical Journal* for December 3d, Dr. Louise Fiske-Bryson takes up a somewhat similar topic. An inquiry was instituted in order to see whether education and cultivation tend to lessen the sexual and maternal instincts in American women. The data obtained are lacking in preciseness, but are sufficiently interesting. Twenty-five "cultivated women," of average or superior intelligence, excellent education, and good social positions, were questioned. Four were physicians, three were engaged in literature, one was "a royal beauty admired of two continents," and three were dignified matrons. They had all been married between the ages of nineteen and thirty-five, and nearly all were mothers. They varied greatly in height, weight, and physique.

Inquiry showed that twenty possessed maternal instincts, eleven possessed both sexual and maternal instincts, fourteen seemed to have no definite knowledge of the sexual instinct or feeling, nine possessed the maternal instinct but not the sexual, while five possessed neither sexual nor true maternal feeling.

Of the twenty-five, only eleven, therefore, possessed capacity for both maternal and sexual feeling. The conclusion drawn by Dr. Bryson, therefore, seems rather a *non sequitur*, for it is this: "Cultivated women of the highest type and of most value to the world are in no wise deficient in natural instincts."

Since fifty-six per cent. of the cultivated women about whom the inquiry was made lacked in sexual instincts, the most obvious inference is that this class of women may have a fully developed nature, but, as a rule, they do not. It is inferred, but not stated, that the eleven fully equipped matrons were the best of the twenty-five, and that among the others there was an element of frivolity in the character which placed them on a lower plane.

It is well known that civilization tends to retard complete functional development, and the inquiries of Dr. Bryson show that the average age at which the (sexual?) instincts were recognized was twenty-seven.

THE ACTION OF MEDICINES AT A DISTANCE.

ABOUT two years ago Drs. Bourru and Burot, Professors in the School of Medicine at Rochefort, published the results of some experiments with hypnotized patients, in which they claimed that certain drugs produced physiological effects when simply brought near the patients. Even toxic effects were noted. Their observations received very little credit, as it was believed that some errors in method must have been made.

In the *Revue de L'Hypnotisme* for October 1, 1887, these gentlemen reiterate the claims they made for a valid discovery, and give some diffuse and inapposite illustration in order to make it appear less improbable.

In *L'Encephale* for September and October, 1887, Professor J. Luys reports somewhat similar experiments. The details are given with great preciseness. The subjects are hypnotized and placed in the stage of lethargy, with neuro-muscular hyperexcitability. Various drugs are placed in different vials, hermetically sealed and numbered. One is taken out of the basket which holds them, the operator not knowing at the time its contents, and placed near or in contact with some part of the subject's person. Peculiar effects result, depending upon the location of the drug and its nature. From the descriptions and illustrations so far given, it does not appear that the specific effects of the drug are always obtained, though this is sometimes the case. We cannot see, in fact, from the evidence at present given, that the subjects do more than experience certain hallucinations, the character of which is purely accidental. It is a significant fact that Professor Charcot refused to serve on the commission appointed to investigate the claims of Professor Luys.

The possibility that drugs can act at a distance in the way they are asserted to do by Bourru, Burot, and Luys is, *a priori*, extremely slight. We have, however, known of a patient who, when a little ill, always sent for his doctor, got the medicines prescribed, set the bottles on the dressing-case, and in a few days was completely cured. This patient argued that such a procedure was the surest way of securing health and, at the same time, promoting the interests and prosperity of the medical art.

FECAL ANÆMIA.

THIS is the title of a paper read recently by Sir Andrew Clark before one of the London societies. The essential ideas expressed were not new, but their grouping was somewhat novel. Under the heading of fecal anæmia the writer discussed the question of anæmia occurring in young girls about the time of the establishment of menstruation. We have usually been taught to regard these blood-changes as due to the general systemic disturbance incident to the inauguration of a new and most important function. We have recognized the exciting causes as well. On these general grounds we have been content to let the matter rest.

Sir Andrew Clark takes up one aspect of the case, and elaborates therefrom a novel and highly probable theory. He alludes to the profound mental and emotional changes occurring in the female sex at the time of puberty. The young girl, who has been only a creature full of mere animal spirits, becomes shy and retiring. Questions of personal physiology force themselves upon her. She shrinks from the contemplation even of matters relating to the hygiene of the pelvic organs, much more from their performance. The importance of regular evacuations is not recognized, and, unless friendly maternal counsel is at hand, she speedily becomes the victim of obstinate constipation. However great the bodily discomfort therefrom may be, she suffers in silence, not daring to ask for relief. As a result of this perversion, or, rather, abeyance of function, the system speedily becomes clogged, effete materials accumulate in the bowel, and there remaining they undergo chemical change. Poisons of the ptomaine and leukomaine classes are formed. These are absorbed into the circulation, and set up a form of systemic infection. This runs a slow chronic course, evincing its presence in the usual clinical picture of paleness, headache, dyspnœa, palpitation, dyspepsia, and the other customary features of anæmia. The old idea made constipation simply one feature of its condition; the new makes it the direct cause.

Of course all cases of anæmia cannot be brought under this category, nor does Sir Andrew Clark make any such claim. Experience shows, however, the correctness of his views in a large proportion of cases. The marked relief that follows from a thorough cleaning out of the bowel is a matter too well known or more than mention. It ensues even before any blood-forming tonics are given, and often the patient seems to improve about as rapidly without as with the latter. The constant absorption of poison being checked, nature regains the upper hand and the vital machinery once more runs smoothly.

It is in such cases as these that excellent results have been obtained by the use of cascara. This drug is distinctly a tonic-laxative, of which the dose can be gradually reduced instead of increased, as is usually the case with laxatives. It restores the normal vitality of the muscular fibre of the gut, exhausted by over distention.

FOLIE GYNÉCOLOGIQUE.

The fact that certain women develop a kind of mania for uterine treatment is well known. These cases haunt the dispensaries or pursue the physician in his office. They are never content unless a vaginal examination is made; and the topical application of iodine to the cervix is to them what a "nip" is to the confirmed toper. They possess a kind of inebriety for local treatment. The condition is sometimes due to a morbid sexual erythism, but oftener perhaps it is a purely mental disorder, and belongs to the "habits." The French call it "folie gynécologique," and the Germans "Mutterleib Krankheit-wahnsinn." It is evidently a disorder coextensive with, and also the product of, modern gynecology. In the West these cases, as we learn from the *Medical Age*, go by the purely Saxon name of "wombcranks." They are utilized by clinical teachers, and are made victims of by dishonest physicians.

What they need is isolation from the doctor.

ANTIFEBRIN AS AN ANODYNE.

Antifebrin appears to have properties that will make the drug valuable as a remedy in the pains attending many nervous affections. Lépine was one of the first who used acetanilide in the painful paroxysms of locomotor ataxia. Dr. Demiéville, in the *Revue Médicale de la Suisse Romande*, gives his experience with the drug in over eighty cases in which fever was absent. He often used fifteen grains in the twenty-four hours, and did not observe any ill effects therefrom. He found that digestive disturbances were quite infrequent. Sweating sometimes occurred, but depression only quite exceptionally.

The anodyne effect of antifebrin was at times noticeable in fifteen minutes, though generally an hour or two elapsed before it occurred. Somnolence was commonly observed.

The author found that the effect of the drug would wear off after its prolonged use, but after being discontinued for several days it acted as promptly as before. Dr. Demiéville employed the drug in cases of sciatica, lumbago, neuralgia of the fifth nerve, intercostal neuralgia, in headaches of various kinds, in pains of obscure origin, in dysmenorrhœa, in tabes, and even such grave conditions as ostitis and uterine cancer. He claims that antifebrin often succeeds when other nervines fail, and warmly advocates its employment in most painful affections, whether accompanied by fever or not.

A New Hospital for Children's Diseases is to be erected in Paris by the Government.

News of the Week.

Dr. Charles H. May has been appointed Visiting Ophthalmic and Aural Surgeon to Randall's Island Hospital, New York.

Extirpation of the Larynx.—At a recent meeting of the Berlin Medical Society, Dr. Hahn gave a demonstration of specimens of laryngeal carcinoma from cases in which he had excised the whole or a portion of the larynx, and at the same time summed up the ultimate results of his operations. He had performed extirpation, partial or total, in fifteen cases. Two of these are to be considered as cured; one was operated upon seven years ago, being then sixty-nine years of age, and he is still living and well. The operation involved the removal of the cricoid cartilage, the greater part of the thyroid, and part of the hyoid bone and epiglottis, the disease being one of carcinoma keratodes. The other patient was operated upon in May, 1886; here the disease was limited, and the removal confined to one-half the larynx. Dr. Semon, under whose care this patient is, wrote to Dr. Hahn that a small prominence had appeared at the site of the tracheotomy wound, which it is hoped is only a keloid of the cicatrix, but it would, of course, be carefully observed. A later report from Dr. Semon said that it had undergone no change. Of the remaining cases, there was only one of which Dr. Hahn had no recent information, but the last accounts were very unfavorable. All the others were known to be dead; but it must be remembered that in all the cases, with the exception of the one alluded to above, the operation had been resorted to late in the course of the disease. He had that day (November 16th) operated on a patient only thirty-six years of age, the youngest of his cases, whose ages ranged from forty to sixty-nine—mostly over forty years. This patient had been suffering from laryngeal trouble for a year, and had been under the care of Dr. Krause. The diagnosis of carcinoma was made by the microscope, and a unilateral excision was performed. (On the 28th Dr. Hahn reports that this case was doing well.) Among the preparations which Dr. Hahn showed at a meeting was one where there had been nine previous operations for recurrence of the growth within the space of eighteen months; yet even to the end the lymphatic glands were never involved in this case. Indeed, he remarked that lymphatic infection is unusually late in laryngeal cancer. The most favorable cases are those of carcinoma keratodes; the least, the softer and infiltrating forms. The latter cases had better not be treated by excision of the larynx, but reserved for tracheotomy when occasion arises.—*Lancet.*

MM. Foà and Bordoni-Uffreduzzi have studied the Microbe of Cerebro-spinal Meningitis (meningococcus), and have found that it is identical with that obtained by Steinberg with saliva cultivations, and described by Fränkel as the pneumonia microbe. The authors invariably met with this micro-organism in cerebro-spinal meningitis. If it is transplanted daily, this microbe becomes a perfect saprophyte at the end of one hundred and fifty days; it will develop in the surrounding atmosphere, and is then harmless. Before this period, and immediately before death, it may be employed for inoculations; these inoculations preserve rabbits from the effects of subsequent and more virulent inoculations. The infection is confined to the region where the virus is inoculated; it assumes an acute or chronic form according to the virulence of the cultivations inoculated. Attenuated virus merely produces inflammation of the noduli, which resembles tuberculosis. MM. Foà and Bordoni-Uffreduzzi believe that this microbe produces a form of pseudo-tuberculosis in human beings.—*British Medical Journal.*

Relative Longevity of Americans and English.—Americans of the middle and upper classes, *i.e.*, those who can afford to get their lives insured, are healthier and longer lived than Englishmen. Such is the result arrived at from a study of the life insurance statistics of both countries covering the period of years since 1874. At twenty the expectation of life of American males is 42.1 years, of English males, 41.1; of American females it is 40.8 years, which is precisely the same as that for English women. After the age of twenty, the expectation of life among American women slightly exceeds that of English women up to the age of forty-seven. After the age of thirty-five the expectation of life of English women is better than that of Englishmen, but in America women have a 6.0 lower expectation rate than men.

A New Combination of Cocaine.—Under date of January 7, 1888, Dr. Andrew H. Smith writes: "Observing the strong acid property of saccharine, it occurred to me that it could be made to take the place of an acid in combination with the alkaloid cocaine, and thus avoid the extremely bitter and disagreeable taste of the muriate, the salt usually employed. With the aid of Mr. B. Frank Hays, the well-known pharmacist of this city, a salt was obtained which is freely soluble in water, and has an agreeable, sweet, fruity taste—a valuable property when the drug is to be employed in the throat, especially in the case of children. The molecular number of saccharine (a better name would be *saccharinic acid*) is 183, that of cocaine 303; combined in these proportions a neutral salt is formed having about eighty per cent. of the alkaloidal strength of the muriate, a five per cent. solution of the first being equal to a four per cent. solution of the second. Experiments are being made with combinations with other alkaloids."

The Gastric Juice in Cancer of the Stomach.—Dr. V. Netschaien, of St. Petersburg, has examined twenty-two cases of cancer of the stomach and œsophagus, and in all instances found that hydrochloric acid was absent from the gastric juice. This confirms the opinion originally put forth by Velden in 1879.

Treatment of Hepatic Colic.—Olive-oil in large quantity is vaunted as a certain cure for hepatic colic due to gall stones. Dr. Just Touatre, of New Orleans, has written an interesting account of self-cure of biliary colic and gall-stones, in the second number of a bi-monthly Roumanian journal (*Archives Roumanies de Médecine et de Chirurgie*), whose editor is M. Georges Assaky. The method of procedure was as follows: At seven in the evening a blue pill of the weight of fifteen centigrammes was taken, and this was followed twelve hours later by the taking, in one draught, of twelve table spoonfuls of olive-oil; a quarter of an hour later a similar dose of olive-oil was taken, and then the patient addressed himself to sleep on his right ride. At nine o'clock the blue pill acted, producing a copious biliary evacuation, but no gall-stones. Three o'clock in the afternoon saw another bilious stool without stones, but from seven in the evening till midnight six stools were passed; the first two contained seventeen calculi of the size of a large pea, of conical shape, grayish-yellow aspect, and soft consistence. Altogether sixty stones were evacuated, and six of these had the volume of an olive, and were of a black color. The passage of these calculi by the cystic and biliary canals was for the most part unattended with pain, a few spasms being felt probably at the time of the movement of the large calculi. An inexpressible relief was obtained from the pains over the liver and shoulder, which had previously caused much distress; the liver also diminished in size. For three months Dr. Touatre enjoyed perfect health, when the trouble commenced again; the olive-oil was repeated in similar fashion, and with the result that eighteen more calculi were discharged by the bowel. Since then he has enjoyed excellent health. He admits that some courage is required to swallow the large doses of olive-oil.—*Lancet.*

Pasteur's Method Simplified.—Dr. Högyes, of Buda-Pesth, has published in the *Orvosi Hetilap* an account of some researches he has made on the protection of dogs from rabies by a somewhat simpler method than that employed by Pasteur. He, too, makes use of the spinal cord of an infected rabbit, but instead of drying it to a gradually increasing extent to obtain various degrees of activity, he merely rubs it up with water containing chloride of sodium so as to make solutions varying in strength from one-tenth to one-five-thousandth. The dog to be protected is injected successively with these, beginning with the weakest. The results appeared to be quite satisfactory, and a complete immunity from rabies to be secured by six of these injections.—*Lancet.*

The Subject of "The Medical Treatment in Aid of the Dying" is one that may easily evoke some cynical comments; for Dr. Munk has written a book on this subject, and a book to show how medical treatment can aid the dying might seem at first glance somewhat superfluous. Dr. Munk's object, however, is chiefly to discuss "euthanasia," and the extent to which physicians may contribute to it, when dealing with incurable and painful disorders. Dr. Munk does not believe that the physician should produce euthanasia in any case, but should simply contribute, by anodynes, etc., to its peaceful approach. This is the view which is ordinarily and rightly taken by the profession.

"Acute Pulmonary Paresis."—At the last meeting of the Medical Society of London, Dr. B. W. Richardson called attention to a class of cases presenting such peculiar features as to warrant, in his opinion, the belief that the symptoms are due to a loss of nerve-power, resulting in acute vaso-motor paralysis of the vessels in the pulmonary area. Though not common, most practitioners, he says, must be able to call to mind cases, diagnosed as pneumonia, where the patient rapidly dies of asphyxia in spite of all that can be done to check the morbid process. The cases alluded to by Dr. Richardson were mostly in women of a neurotic type. Under the influence of a physical or moral shock, not necessarily of any great intensity, nervous phenomena of a hysterical type manifest themselves, followed by intense prostration of body and mind. In the course of a day or two examination reveals the advent of pneumonic râles, and then, without fever, for the most part without pain, and without many of the characteristic signs and symptoms of ordinary pneumonia, the patient rapidly succumbs. Treatment in every case is utterly without avail.

Dr. Richardson's view of the pathology of these cases is incorrect, because the pulmonary vessels have no vasomotor nerves.

THE ALUMNI ASSOCIATION OF THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.—The third annual meeting of this body will be held at the New York Academy of Medicine, January 18, 1888.

DR. PETER PARKER died at his residence in Washington, after a lingering illness, on January 10th, in the eighty-fourth year of his age. Dr. Parker was United States Minister to China thirty years ago, and has resided in Washington since his return to this country in 1858. He held the office of Regent of the Smithsonian Institution for many years. While in China Dr. Parker did much work as a medical missionary, and was in fact a pioneer among this class of laborers.

A FURTHER INVESTIGATION as to the germicidal properties of iodoform has been made by Dr. J. Amory Jeffries, at the laboratory of the Harvard Medical School (*American Journal of the Medical Sciences*). Dr. Jeffries, as a result of his experiments, concludes that iodoform has no direct action as a germicide, a result agreeing with Heyn and Rovsing; also, that germicidal products are, probably, not derived from it in the presence of growing bacteria. On the other hand, the experiments with bouillon showed that the presence of iodoform markedly retards the growth of bacteria, an action not before proven, and diminished the foul odors of putrefaction. The diminution in odor cannot be ascribed to the action of iodoform on the bacteria. Looked at from the clinical side, the following rules may be accepted: 1. Iodoform not being a germicide, is not a fit substance to use to procure asepsis of instruments, materials, or wounds. 2. Iodoform is allowable, with the present state of our pharmacopœia, in infected wounds where the true germicides are contra-indicated, as by danger of poisoning or impracticability. 3. As has long been known, iodoform has a decided tendency to stop serous oozing, and, therefore, may be indicated in wounds where the moisture threatens the integrity of the aseptic or antiseptic dressing.

THE SALIVA AND THE LIVER.—Dr. Samuel Fenwick has published a series of lectures in which he reports the results of his examination of the saliva for the sulphocyanide of potassium. The larger or smaller amount of this salt bears some relation, in Dr. Fenwick's opinion, to the digestive and assimilative processes. The saliva was tested by the quantitative color-test in some thousands of cases, and it was found that in the course of febrile diseases, such as typhoid fever, a sudden increase in the quantity of sulphocyanide generally preceded a rapid improvement and a short convalescence, while a small quantity indicated the reverse. The same phenomenal increase was noticed when sudden demands for reparative needs threw an increased increment of duty on the assimilative functions, as, for example, after copious hemorrhage. Under these circumstances it would naturally be expected that the sulphocyanide would be deficient whenever the digestive organs are unable to supply the nutriment sufficient to meet the requirements of the system, and this was found to be the case in the vast majority of patients dying from wasting diseases.

DENTAL CARIES IN CLARIONET-PLAYERS.—In the *Vratch*, Nos. 30 and 31, 1887, Dr. P. Reformatsky, of Ekaterinoslav, publishes a valuable contribution to the study of professional diseases of the teeth. The author, who is surgeon to the Simferopolsky Infantry Regiment, has examined the teeth in bandsmen of his own and four other regiments. He found dental caries in about fifty per cent. of the men, but he was especially struck with the great frequency of a characteristic caries of the upper central incisors which was present in fifteen of twenty clarionet-players belonging to two regiments. In playing, the mouthpiece of the instrument is pressed against the outer surface of the lower lip, which then forms a kind of soft protecting cover for the lower teeth, while the upper aspect of the mouthpiece is kept in direct contact with the upper incisors.—*British Medical Journal.*

THE COLD WAVE which struck this city lately has been followed by an unusual amount of bronchitis and pneumonia. According to the theory of Dr. Baker, of Michigan, those who wish to avoid pneumonia should eat but little salt.

THE HANDS OF SAN FRANCISCO DOCTORS call for some severe criticism on the part of the *Pacific Record of Medicine and Surgery.* Speaking of the many persons lacking in refinement and education who undertake the study of medicine, the editor says: "Take some of the physicians in our city; look only (for example) at their hands. What woman would like to have one of them introduced into her vagina? See the finger ends and the nails, swollen and dirty, and if she is educated in the modern bacterial physiology, she will understand that under the finger nails may lurk the streptococci or bacilli, which will inoculate her with a disease that will insure the doctor many visits and consequent fees. The hands, feet, and facial expression mark the man of gentle birth, externally. The tender sympathy, the gentle touch, the instantly conveyed magnetism, that does not shock the most sensitive fibre of the female economy, but yet gives the assurance of perfect *rapport* with her trouble, mental and physical, and which opens the way to a perfect understanding of her needs and sufferings; shows to her the workings of the man's consciousness. Who shall dare enter into the temple of a woman's soul, but a man with 'clean hands, and a pure heart?' How few graduates of our medical colleges can stand in those 'holy places?'"

HUMIDITY, COLD, AND HIGH WINDS, are the three agents that chiefly promote the prevalence of pneumonia, according to Dr. Seibert, and February is its carnival month.

Obituary.

WESLEY M. CARPENTER, M.D.,

NEW YORK.

> "To live in hearts we leave behind,
> Is not to die."

When Death enters a circle, we are more than ever impressed with the awe and mystery of his presence. It brings us closely to the veil which drops between mortality and eternity, and leaves us with the yearning for another word, another look, another touch. It is therefore with an inexpressible sadness of heart that we are called upon to record the departure of our old and beloved friend, and our honored and trusted associate. The hundreds who knew him personally and the thousands who knew him by reputation will join in saying that one of the most conscientious and faithful workers in medical journalism has passed away. It is indeed difficult to estimate the loss which has been sustained. For fifteen years he has been a member of The Record family, and a continuously active worker on its staff. His facile and tireless pen has been busy in various departments, but more particularly in that devoted to society reports. His skill and aptitude in the latter were never equalled, as every one who ever read a paper or discussed a topic before a medical society can abundantly testify. Every speaker felt himself more than safe in his hands. Dr. Carpenter was always proud of this trust, and always did his best to deserve it. The soul of truth and honor, he knew no friends or foes in a discussion, but was always ready to tone down asperities by a loving charity for all. Firm in his convictions as to duty, his constant aim was to be truthful and just, and so he was to the end one,

> "Whose yesterdays look backward with a smile."

Dr. Carpenter was born in Erieville, N. Y., August 2, 1839. In his early youth he assisted his father in work upon his farm; but becoming imbued with the love for study, prepared himself for and afterward entered an academy in the neighborhood. After this training he began the study of medicine, in Ann Arbor, Mich., completing his course and graduating at the College of Physicians and Surgeons (1863). Subsequent to this he practised medicine in Erieville, N. Y., in partnership with Dr. Greenwood. He was elected to the Assembly in 1869, and served the term.

The labor and exposure of a country practice being too severe for his delicate health, he moved to this city in 1872, with a determination to devote himself to literary work, for which he had a great aptitude. It was then that we first met him. His offer of services to The Record was gladly accepted, and from that time until his death he was our faithful helper, and tried friend. His universally recognized ability as an accurate and accomplished short-hand reporter peculiarly fitted him for his many duties as chief of our reportorial staff. There was no work in his line, however difficult or abstruse, with which he could not be trusted, and for years his was the familiar presence at every City, State, or National medical gathering of any importance. It was enough for us to know that Carpenter was there; and no matter what were the obstacles, a truthful and accurate report by mail or the telegraph would always be forthcoming and timely.

His greatest work in this line was the full report of the late meeting of the International Medical Congress, which stands alone as the most complete and most accuràte account of any scientific meeting that has ever been held. It was in reality a volume prepared in a few days, a triumph of enterprise even in this age of telegraphy and rapid reporting. His wide and careful training in medicine fitted him for such an undertaking; and his rare judgment for selection of the useful always served his purpose of focalizing the gist of any discussion, or of formulating the practical points of any author.

His varied talents as a ready writer were always in demand, and he became in time practically, if not in fact, a universal and omnipresent secretary to almost all the leading medical societies. He was Secretary to the New York Pathological Society, Corresponding Secretary to the New York Academy of Medicine, Secretary to the Medical Society of the County of New York, and Acting Secretary to the Practitioners' Society of New York.

With a view of varying his duties and obtaining recreation, which he did only by change of work, he accepted the position of Curator to the Bellevue Hospital, became Instructor in Histology, and, lastly, Clinical Professor of Medicine in the Medical Department of the University of New York.

He was, besides, author of the "Index of Medicine," which has become a very popular work with busy practitioners, and which contains more practical and well-digested information than any work of its size ever published. He was also the editor-in-chief of the *Epitome of American Medicine and Surgery*, which, under his guidance, assumed a new rôle of usefulness and an extended patronage. Busy as he was, he also found time to contribute articles to the "International Cyclopædia of Surgery," to edit "Wood's Handbook of Medicine" and "The Medical Record Visiting List."

In 1879 he married Mrs. C. F. Shorey, who shortly after removed to Paris to complete the musical education of her daughter Nettie, who assumed her step-father's name, and who has since taken a position as a leading violiniste in Mr. Abbey's concert troupe. Mrs. Carpenter and daughter were temporarily absent in Providence when the doctor's death occurred.

Dr. Carpenter was never robustly healthy, but none of his friends suspected that he was suffering from serious disease until his sudden death occurred. At the autopsy, disease of the kidney was found to be the cause. His passing away was peaceful and sudden, he having been found dead in his bed on Saturday morning, January 7, having retired the evening before apparently in his usual health. His sleep merged itself so quietly into the lasting one that Death said not,

> "Good night, but in some brighter clime
> Bade him, 'Good Morning.'"

The funeral services, which were largely attended, were held at the Methodist Episcopal Church, corner of Twenty-second Street and Fourth Avenue, of which he was a member, and his remains were interred in the Cemetery of the Evergreens, N. Y.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

SECTION IN SURGERY.

Stated Meeting, December 12, 1887.

ROBERT F. WEIR, M.D., CHAIRMAN.

DR. CHARLES A. POWERS presented a specimen of

BLADDER RUPTURED BY FRACTURE THROUGH THE RAMUS OF THE PUBIS.

The patient, a boy aged fifteen, fell thirty feet through an open hatchway, and was immediately carried to the Chambers Street Hospital. He was in profound shock, and was found to have a fracture of the left humerus, fracture through the horizontal ramus of the left pubis just without the symphysis, and fracture through the left ilium just outside the sacrum. A catheter introduced into the bladder withdrew six ounces of bloody urine, the blood being well diffused.

Weir's method of testing the bladder was employed, about ten ounces of warm water injected and allowed to remain ten minutes, and then withdrawn. All but about two drachms returned. There were no evidences of other injury.

The patient never completely rallied from the shock, but continued in a state of profound exhaustion, and died in sixty-four hours. The hæmaturia had completely disappeared at the end of twenty-four hours.

At the autopsy the viscera, with the exception of the bladder, were found to be normal. The bladder was the seat of a punctured wound of a size admitting a small probe, and situated in the anterior wall at about its middle, just to the left of the median line. It had been produced by a sharp spicula of bone from the ramus of the pubis. The wound was occluded by lymph. There was no degenerative inflammation.

The case was of interest as showing that in a wound of this size the bladder would hold water even when well distended.

Dr. Powers also presented specimens of

RUPTURED SPLEEN, KIDNEY, AND LIVER.

They were taken from the body of a woman fifty-two years of age, who was admitted to the Chambers Street Hospital on the evening of September 17, 1887, with history of having fallen from a second-story window to the ground fifteen minutes previously. When admitted she was in a state of intoxication, but her general condition was otherwise good. She had sustained a compound comminuted fracture of the left elbow-joint, and a fracture of the neck of the left femur. Examination of abdomen and thorax revealed no evidences of lesion. The urine contained about ten per cent. of albumen.

The following morning she was conscious; her general condition was perfectly good; the pulse was 90; temperature, 99° F.; respiration, 16.

The elbow-joint was excised by Langenbeck's method.

During the two succeeding days her condition continued good; the pulse averaged 84, but the temperature and respiration were normal. She slept considerably, but was easily roused, and made no complaint.

On the afternoon of the third day she suddenly became restless and weak, the pulse became rapid and feeble, the temperature went up, and in a few hours she died.

Upon autopsy, the abdominal cavity was found to be full of clotted blood and bloody serum. All viscera were normal except the spleen, liver, and kidneys.

The spleen presented one rupture two inches long on its antero-external surface, and another one and a half inch long just within this.

The liver presented several small intra-capsular ruptures on its superior surface, while on its inferior surface were several small lesions extending through the capsule.

The left kidney presented a deep transverse rupture on its posterior surface, together with several smaller ruptures.

Dr. Powers thought the case interesting as showing that a patient could live three days with such severe internal hemorrhage and visceral lesions, but with absolutely no guiding symptoms. It also shows that a deep rent of the kidney may exist without hæmaturia.

THE CHAIRMAN said that the mere introduction of a quantity of water into the bladder and then measuring that which returned was an old method. But the distention of the rectum recommended by Petersen, together with the bladder-distention, were what enabled him to mark the rise of the bladder above the pubis, which was the most important point, and it was to that point he had called attention in his paper.

DR. R. T. MORRIS remarked that it was necessary for the water to remain in the bladder for at least half an hour to permit any of it to escape, in case of punctured wound of the bladder.

DR. DIXON JONES then opened the discussion on

THE TREATMENT OF OBSTINATE CLUB FOOT BY OPEN INCISION.

He first described the factors pathological and mechanical which entered into the production of this deformity, and which showed the difficulties to be overcome in the treatment of these cases. The shortened soft parts retained the distorted foot in its abnormal position, and each structure must receive the proportionate share in the treatment. He believed that these tissues could be best dealt with by the open incision, the method devised by Dr. Phelps, and practised by Schede, Volkmann, and others. He laid special stress upon the importance of the preliminary manipulation, softening the tissues, etc., before the operation, which he then described in detail, reported illustrative cases, and presented patients with photographs of the feet before and after the operation.

DR. C. T. POORE said that the astragalus in the infant differed in shape from that of the adult in that the long axis of the neck pointed much more inward in the former than in the latter. Measurements made by Parker and Shattuck showed that in eleven specimens taken from infants with normal feet the obliquity of the neck had a mean angle of 38°, while in twenty measurements of the adult bone the mean angle of obliquity was only 10.65°, the majority being under 10°.

It was evident, then, that during growth the angle at which the neck was set upon the body of the bone changed from a mean of 38° to 10°, which might be called the normal development of the astragalus. All children at birth exhibit a certain amount of varus.

Dr. Poore then presented a specimen with photograph, loaned to him by Dr. J. B. Bissell, which showed the form of the astragalus in a child eight months old with normal feet. The head and neck were set upon the body of the bone at an angle of 28°.

Another specimen from the foot of a boy ten years o age, with normal feet, showed an obliquity of 14°. In this case the bone presented the adult peculiarities.

Another specimen from Dr. Bissell's collection, taken from a child eight months old,

WITH MARKED CONGENITAL TALIPES VARUS,

showed that the bone differed in a marked degree from that of the normal foot. The neck was set upon the body at an angle of 60°, and it presented other marked peculiarities.

In the two feet of children with varus, exhibited by Dr. Phelps at the last meeting of the Section, the astragalus varied from the normal type, and the os calcis exhibited an abnormal curvature with the convexity looking outward and the anterior articulating surface looking forward and inward.

Dr. Poore then described the condition of the astragalus in other cases in which Parker and Shattuck had made measurements; also the changes in the ligaments and tissues on the inner aspect of the foot in varus.

When the period had been reached in which the astragalus and os calcis had ceased to be cartilaginous, and then the shortened tissues upon the inner aspect of the foot were relieved either by division or stretching, it would be found that the front of the foot was swung on the elongated os calcis as a centre, so that the scaphoid was drawn away from the position that the head of the astragalus should occupy and a permanent restitution of the foot was a mechanical impossibility. He then exhibited, by the kindness of Dr. R. J. Hall, an astragalus removed by Dr. Sands from a child six years of age for the relief of congenital talipes varus. The neck was set upon the body at an angle of fifty-five degrees, and there was also a deformity of the neck downward. It was evident from the specimen that correction of the deformity without a radical operation was impossible. Other specimens and photographs were exhibited.

In speaking of the infantile astragalus, he did not intend to convey the impression that he would advocate an osteotomy in a child six years of age, his purpose being only to prove changes in the shape of the bones was an element in congenital talipes varus.

In a paper read before the Surgical Society, December 8, 1886, and published in the New York *Medical Journal* for January 15, 1887, on "The Treatment of Inveterate Talipes Equino-varus by Osteotomy," he said that the real deformity in this class of cases was behind and not in front of the medio-tarsal joint; and, 1. That the inability to correct the deformity was due to changes taking place in the astragalus and os calcis. 2. That, in order to bring the anterior portion of the foot into its normal position, the curvature in the os calcis must be removed and the neck of the astragalus shortened, so as to allow its head to point in its normal direction and thus carry with it the scaphoid and other tarsal bones. The operation consisted of removing a **V**-shaped section from the anterior portion of the os calcis base outward and shortening the neck of the astragalus by the removal of a wedge-shaped piece so as to allow the head to point in its normal direction; in other words, to restore, as far as possible, that bone to its adult shape.

He thought that, from the specimens exhibited both by Dr. Phelps and himself, as well as from the anatomy of the deformed bone recorded by Adams and others, there was in most cases a marked variation from the normal type in the astragalus, and that it was an element, if not of the cause yet of the persistence of this deformity in children over four years of age; that the reason why either a division or a stretching of the shortened structures on the inner aspect of the foot was necessary for the permanent correction of the deformity was due to the fact that it released the head and neck of the astragalus from the confined position in which these tissues bend and hold them, and thus gave the bone a chance to grow and develop.

There was a question whether as free an incision as was advocated at the last meeting was a necessity, or whether a subcutaneous section of the shortened tissue would not be all that was required.

Dr. Lewis Hall Sayre thought that the cases presented by Dr. Jones were not relevant to the discussion, because Dr. Phelps proposed to adopt the open incision only in such obstinate cases as had resisted manipulation and mechanical treatment. He regarded Dr. Phelps' operation as safer than Dr. Poore's section of the os calcis or tarsotomy, etc.

From what he had seen of

RELAPSING CLUB FOOT,

there were two classes of cases: First, those in which tenotomy had not been properly performed; and second, those in which it had been held that the talipes was cured by the operation.

It should be borne in mind that in talipes there was not only shortening of all the tissues on one side of the foot, but a relaxed and weakened condition of the muscles and other tissues upon the opposite side, and not until, by appropriate treatment, those weakened structures had been so restored as to enable the patient voluntarily to bring the foot into its normal position and retain it there could the case be said to be cured. If allowed to go, after an operation, without treatment, relapse would take place in a very large proportion of cases.

In one or two of Dr. Jones' cases he had noticed a slight varus, very slight, it was true, and to be easily overcome, but it might possibly become a serious deformity.

He had, in some cases, divided the skin freely where it seemed to be the tissue that resisted the proper correction of the deformity, and as already stated he favored Dr. Phelps' operation by open incision rather than the more formidable ones of tarsotomy, etc.

Dr. V. P. Gibney said that the question of what tendons or muscles or ligaments should be cut could be safely left to the individual judgment of the surgeon. The only suggestion which he wished to offer in addition to what had already been said concerning operative measures was that

TOO MUCH STRESS COULD NOT BE LAID UPON AFTER-TREATMENT.

Whatever might be the claims concerning bony deformity, it must be assumed that there was an immense amount of work to be done to produce atrophy on the outer side and hypertrophy on the inner side of the foot. If Dr. Phelps, by his operation, could remove the pressure from these bones, which were growing then, it was a justifiable and good operation. He thought that the brilliancy of many operations tempted to the omission of subsequent mechanical treatment. It was all well enough to talk about pressure produced by braces and pads, etc., but the sooner mechanical and operative treatment could be combined the better would be the results ultimately obtained.

In Dr. Jones' second case, as Dr. Sayre had said, there remained some varus; but the child was not sufficiently old to know enough to turn the toes out when it walked, and the only way to impress the child with that necessity was to apply some apparatus which would prompt this movement, and in time produce atrophy of the hypertrophied bones and compensatory hypertrophy on the inner side of the foot.

The remarks made by Dr. Poore on the necessity of recognizing the osseous element in these cases were very pertinent, and he would also say that it was his intention to employ Dr. Phelps' method in certain cases. He wished to reiterate that to retain the foot in the best possible position for two, three, or five years, after operative treatment was very essential to obtaining ultimately good results in these cases.

Dr. N. M. Shaffer sent his views in writing, which were read by the Secretary. He maintained that the inveterate cases of club foot yielded to simple traction, although apparently simple cases sometimes required operative treatment. Surgeons looked upon the subject from widely different stand-points, and he thought they were frequently inclined to adopt pessimistic views concerning other methods employed in these cases. The open incision was advocated almost exclusively by Dr. Phelps. But it was also very exceptional to find a case of congenital club foot which had not been operated upon, although failure was the rule after tenotomy and other conventional methods. It was not surprising, therefore, that osteotomy and the open incision should be employed to correct the deformity. But in his opinion, based upon his own experience and study, neither the open incision nor osteotomy was required to effect a cure.

He divided club foot into three distinct varieties: (1) Muscular, (2) ligamentous, and (3) bony. It was exceedingly difficult to differentiate between these, and, even if we could, the extreme measures of treatment would be called for only rarely. His method was to employ traction, and if that failed to divide tendons and other resisting structures and then apply traction, and so go on until it became certain that the case could not be cured by that method of treatment.

Dr. A. G. Gerster said that his experience was not sufficiently large to enable him to formulate any permanent conclusions, as he had operated by the open incision in only six cases, two of which were too recent to enter into the calculation.

The several gentlemen who had given their views, it seemed to him, had spoken with a remarkable degree of unanimity. Dr. Shaffer had given the position which most surgeons occupied, inasmuch as he had said that a great many cases will yield to mechanical treatment, that others require tenotomy, and that still others may require osteotomy. All cases, as pointed out by Dr. Gibney, will require long-continued treatment to achieve permanent results.

He could not conceive that in those cases in which the operation was not fully indicated that it would be performed, or if there was any serious cause for opposition to it. With the aid of antiseptic surgery the method by open incision could be adopted without special danger, but it was not so easy to decide concerning the operation. Everyone would acknowledge that it was extremely difficult to say when the operation in these cases was or was not justifiable, because at present there was lack of exact criteria by which it could be said that this case would require operation and that one would yield to mechanical treatment.

The great advantage of operative treatment was that it enabled the surgeon to accomplish with the knife at once what could be done otherwise only by a great expenditure of time and patience and money. The question had been properly raised, Should such a long trial by mechanical means be gone through with? As a surgeon, he would say that as the operation did not involve any serious danger it was unnecessary to first resort to traction and mechanical treatment, and he was inclined to try the open incision to test its value. He warmly indorsed the long-continued after-treatment. To speak of the method of allowing the wound to fill with blood to become organized as Schede's or Morris-Schede's, he thought should be modified somewhat, inasmuch as Schede had simply shown that

CAVITIES DO BETTER BY ALLOWING THEM TO FILL WITH BLOOD-CLOT TO BECOME ORGANIZED.

The organization of blood-clot was known as far back as 1874, was described by Volkmann in 1875, and it had also been described by Lister. Schede had proved by autopsy that, notwithstanding the gaping to the extent of an inch or an inch and a half, union of the divided parts took place in the physiological order, muscle with muscle, tendon with tendon, etc.

Dr. A. B. Judson preferred to take the strongest possible ground against the operative treatment of club foot. If every case, congenital or acquired, were treated mechanically, as it ought to be, there would be no question of an operation. And after the operation was performed the necessity of painstaking, thorough, and prolonged mechanical treatment was as urgent as it was before. He had never seen a case in which the mechanical treatment had not seemed to him of more importance than any possible operation. He thought that the question of the success of an operation for obstinate club foot could not be determined until a long time had elapsed after its performance. The condition itself was the result of neglect on the part of the parents. What guarantee was there in the performance of an operation that the neglect would cease, and that another would not be added to the large number of cases of obstinate club foot which persisted after repeated operations?

Dr. Reginald H. Sayre directed attention to the principle laid down by his father, which would serve as a guide in deciding when to operate, and it was that when any contractured tissue was put upon the full stretch, and point-pressure upon it while thus made tense caused spasm, that tissue could not be stretched any further, but must be divided either with the knife or by mechanical force. He believed that section was preferable to rupture, and whether that should be made openly or subcutaneously must be decided by the operator. He thought that cases such as the one Dr. Phelps operated on at the last meeting of the Section would do as well under subcutaneous section as the open incision. In older persons the operation was undoubtedly an excellent one, and should have its place among others as one of the

ADVANCES IN SURGERY.

Some of the patients presented he had noticed showed considerable valgus, and he feared that when they had grown up they would be travelling about with a broken arch.

The Chairman said that, from his experience and what he had seen of Dr. Poore's and Dr. Phelps' methods, he felt it was well to proceed with operative interference without waiting a long time. His preference would be, in doubtful cases, to adopt Dr. Phelps' method first, on the general basis that operations involving bone were more liable to be followed by mishaps, even with the benefits which antiseptic surgery afforded, than those in the soft parts.

Dr. Gibney wished to correct a possible misapprehension by saying that he did not believe in prolonged mechanical treatment. If the deformity could not be rectified soon, he called to his aid operative measures, and then used such simple mechanical apparatus as could be readily managed by the parents or friends, thus obviating the necessity of his seeing the patients oftener than once in three to six months.

Dr. Gerster said that he spoke as he did simply because some of the gentlemen had said that operative treatment was not necessary. He knew very well that Dr. Gibney practised operative interference. He had, however, seen cases treated by mechanical appliances for a long time without the least improvement.

Dr. Phelps, on account of ill-health, was unable to enter into the discussion, and simply reported that the patient operated upon was doing well. His effort had been to place before the profession a method of treatment by which the deformity was unravelled, beginning with the skin and going on step by step, and terminating with osteotomy if necessary. All that was necessary was to get

THE FOOT INTO A POSITION READY FOR TREATMENT,

as the treatment of club foot did not begin until the foot was straight.

Dr. Robert T. Morris then read a paper on

FRACTURE OF THE FIBULA FROM ADDUCTION OF THE FOOT,

in which this injury was compared with Pott's fracture, produced when the foot was abducted with sufficient violence.

The Chairman thought the distinction should be made, although, as Dr. Morris had said, both varieties were usually recorded in hospitals as Pott's fracture.

Dr. Powers regarded the fracture as one of common occurrence and most frequently regarded as a sprain, because the patients had been able to walk.

Dr. Kearney had seen five or six cases in which fracture of both malleoli had occurred, and yet the patients had walked upon the foot for three or four days.

Dr. Girdner was surprised to hear the intimation that any surgeon might confine his patient to the bed and treat a case of fracture in a fracture-box until its termination.

THE CHAIRMAN said he could not help speaking a word of sympathy with Dr. Girdner's surprise, because he had not seen, or at least used, a fracture-box during the last ten years.

The Section then adjourned.

Correspondence.

"THE FAMILY PHYSICIAN OF THE FUTURE," AND "EUROPEAN OPINIONS OF AMERICAN PHYSICIANS."

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: No one can peruse without pleasure and advantage the paper with the first of the above headings, read by Dr. A. H. Smith before the Academy of Medicine, November 17, 1887, and published in THE MEDICAL RECORD of December 3d. Nevertheless, Dr. Smith's delineation of the family physician, as he exists in New York, does not correspond to this personage as I know him, nor, in a general practice of nearly thirty years here, have my own experiences and position been at all like those described by Dr. Smith. If they were, I should feel bound to seek at once "fresh fields and pastures new."

Admirable as is the paper referred to, it is, I think, too insular, making New York, or this country, the standard of the physician's power the world over. It describes too truthfully, alas! the limited influence, as it exists *here*, of the physician in directing matters pertaining to public hygiene, and in public life, letters, etc. But as regards the physician's position generally, I think Dr. Smith's paper is erroneous, in what manner I will endeavor to show, and also why some of the unfortunate conditions described *do* exist. I am sure, however, that even here the family physician exists with as much distinctness as does the oculist or dentist; and I believe it to be the exception when respectable families who possess good intelligence desire the aid of specialists without his suggestion or sanction, and who do not have sufficient confidence in him to leave to him the treatment of nearly everything that he considers himself competent to treat. I certainly cannot say that none of my families ever consult specialists unknown to me, but I know that as a rule they leave to my judgment the necessity of calling in aid, and I believe this to be the rule in family practice generally; indeed, the supplication, "Oh! do not send me to a specialist," is one that I often hear. Certainly, the family physician still exists in his entity, and, speaking of New York alone, I believe his opportunities of doing good in the sick-room are as great as ever, and his influence is none the less because specialists are increasing in number. When we consider how wide is the field of disease, it is apparent that the great bulk of cases which need treatment are such as naturally fall under the care of the general practitioner. The numerous ailments of children; the functional and minor organic ailments of women; the fevers; gouty, rheumatic, renal, and hepatic troubles; the affections of the thoracic and abdominal organs; the innumerable ills, in a word, "which flesh is heir to," are quite enough to make the field of the family physician a very extensive one. None of the numerous babies I have attended have yet called for a baby specialist, and it is the cry of most of my lady patients not to send them to a gynecologist.

The family physician should, as a rule, be competent to make all examinations of the lungs, heart, liver, kidneys, nervous system, etc., and to treat them, though there are many occasions when the aid and advice of a specialist might be indispensable, and no one appreciates more than myself their valuable aid in such cases.

This advantage the family physician often has: A knowledge of the habitual ailments and constitution of the patients, acquired sometimes by years of observation, and his study of the particular case often leads to a more accurate knowledge of it than is evinced by the sometimes *ad captandum* diagnosis of the specialist. I believe, however, that even here the family physician is still the honored visitor, and that the tradition of respectability attaching to his position and relations with the family have not yet disappeared.

As regards the voice of the physician in legislation: That it is not heard oftener in the legislative hall here is not that the profession *as* a profession is looked down upon or considered useless except in the direct care of the sick. In France, for instance, I remember that there were at one time at least as many as fifteen medical men in the Senate and Corps Législatif, there being in the former, at the same time, Nélaton, Rayer, and the Baron Larrey. More recently Paul Bert, Clémenceau, and Cornil have been members of the Corps Législatif. As regards general science, the Institute of France, devoted to every branch of science, and as exclusive as regards difficulty of membership as l'Académie Française, has seventy-seven members; eleven of these are medical men, among whom are Pasteur, Brown-Séquard, Charcot, Richer, and Ranvier.

The Conseil d'Hygiène Publique et de Salubrité has for its object the protection of the public health. It numbers thirty-nine members; of these twenty-four are medical men, among whom may be mentioned Bouchardat, Dujardin-Beaumetz, Ollivier, Richet, and Pasteur.

The Committee of Public Hygiene of France is composed of twenty-eight members; of these more than one-half are physicians. The Administration Générale de l'Assistance publique has entire charge of hospitals, hospices such as La Salpétrière and Bicêtre, domiciliary aid, markets, and general health. There are seven physicians in this body.

Certainly, however, the position of the family physician in London and Paris is, on the whole, better than here. In Paris the doctor is looked upon as the family friend—*l'ami de la maison*; "mon docteur" is revered as much as the priest, if not more. His bills are "preferred" and paid as a matter of honor. His directions are implicitly followed, and patients do not ask what they are taking. In London no very prominent physician, though he may have office-hours daily, can be seen except by appointment with his servant; this is very much to the patient's advantage, as he is sure of being seen without waiting much, and a certain amount of time is allotted to his case. Abroad the family physician is likely to be selected for some sort of credentials of capacity, or because he has "done something," or given evidence of work.

Here a large number of people have but a very dim idea of why they consult a particular physician; sometimes it is because he is young or old; because he drives two horses, or because he drives but one; because his charges are low, or because they are high and must necessarily indicate talent; because he is a professor, or because he is not; because his name appears often as a laudator of wines and mineral waters, but not often enough because they know him to be educated, faithful, and competent.

A principal reason of the position of the medical man in France, and especially in Paris, is that in that city the doctor of medicine is, and must of necessity be, a learned man. To matriculate in France one must be a Bachelor of Science or Arts, and in Paris must study six years before he can obtain the medical degree. The examinations are severe and public, and favoritism is impossible. To become an interne, or a physician to a hospital, or a professor agrégé in the faculty, making him eligible to a full professorship, there are more theses or more examinations, no matter how renowned the candidate. In France no medical grade can he obtain except for merit and distinction, and usually by competition. The medical atmosphere there is clearer. Abortions by medical men (though happily rare here) are almost unknown, and the recommendation of foods, waters, etc., except in medical journals, almost, if not quite, unknown. There are in all France but six bodies entitled to confer the right to practise, namely, the Faculties of Paris, Lille, Lyon, Nancy, Montpellier, and Bordeaux.

In the United Kingdom there are about eighteen, while in the United States there are not far from one hundred. In France the number admitted to the medical degree is small, and is growing smaller; in 1883 there were 662 diplomas conferred; in 1884, 590; in 1885, 575; in 1886, only 546. Here it is enormous and needless. The band of music, the address on medical topics by a layman—usually a clergyman—the swell and swagger at our medical Commencements are well known. As long, however, as most of our colleges are dependent on the fees of students, and so long as it is easy for any reputable body of men to establish a medical college under the general law, and as long as students are matriculated without preliminary examinations, and can be graduated often after only two years' study, so long will exist the present disparity between position of the medical man here and abroad. In New York there is one physician to about 400 people; in Paris one to about 1,475. In the whole of France there is about one physician to 3,000 inhabitants; in England one to every 1,500, and in the United States one to every 750.

The result here is often anarchy among our patients. I believe our growing and important Academy of Medicine could undertake no more useful task than to use its influence in making the right to practise medicine less accessible. The medical schools should all require entrance examinations, in which, among other things, a good knowledge of Latin should be included, and there should be a graded course of not less than three years. All of these reformations must come in time, however, and some of our colleges are setting, and have set, a noble example of thoroughness in every essential. I believe the power to practise should be conferred only by a State Board after examination, the medical colleges bestowing, however, the doctor's degree. This restriction of their functions would in nowise interfere with their dignity, influence, nor income.

The same number of THE MEDICAL RECORD which contained Dr. Smith's paper contains also a letter by Dr. Louis Fischer, entitled "European Opinions of American Physicians." Numerous visits and a great deal of time passed abroad, some of it in practice in Paris, have not shown me that the American physician is regarded with the contempt that Dr. Fischer states. Our system of medical education; absence, as a rule, of proper qualifications for admission; professors as numerous all over the land as colonels; short terms of study, and the easy examinations that prevail in many colleges are certainly regarded with contempt, tempered, however, by some incredulity. Nevertheless, the fact is recognized abroad, at least in Paris, that many American physicians have had, or have made, opportunities, and are regarded with respect and deference. Especially is this the case in France, to my mind the most liberal and catholic of all countries in science. Any one who is well acquainted with the leading French physicians will bear witness to the fact that they recognize here many zealous and able *confrères* in medical work. They weed out the tares, however, and are not imposed upon by simple compilers of books, professorships *et præterea nihil*, nor would the reputation that a physician had a large practice have much weight. But I have repeatedly heard our brilliant specialists spoken of in the most eulogistic terms by men whose praise is worth having. As I cannot mention all the former I will mention none, but will say that among those who have passed away the names of Sims, Gross, and Carnochan are held in great honor. I do not know many German physicians, but I know that in Austria many here are held in the highest esteem. That "the American physician is treated in Europe with contempt, and is regarded almost as a non-entity," is an assertion quite incorrect, and, from my experience, seems quite monstrous. The large number of medical works by American authors, translated and published abroad, is a sufficient refutation of this.

Dr. Fischer also states that "every possible obstacle is laid in our way" (to the practice of medicine); but the same rules are applied to *us*, in France, for instance, that are applied to the Germans, English, etc., and to the French themselves. In order to acquire the right to practise there, the examinations of the whole course must be passed, no matter how experienced and able the practitioner. During the empire, and until within a few years, the Minister of Public Instruction could, upon suitable recommendations, give the right to practise. Sims acquired the right in this way. At present this privilege cannot be obtained except by examination. *We* are not singled out, however, as subjects for oppression. There are no more restrictions laid upon us than upon other nationalities.

FAMILY PRACTITIONER.

LOCAL TREATMENT OF PULMONARY DISEASE.

To the Editor of The Medical Record.

SIR: In your editorial of December 3, 1887, on the local treatment of pulmonary disease, you make the following statement: "The defect of the cabinet in connection with the introduction of sprays, etc., is that while these may be deeply inhaled, they are not so completely exhaled, the increased amount of air drawn into the lungs being residual rather than tidal. It seems that the ideal cabinet should have a negative pressure during inspiration, a positive during expiration. Sprays and inhalations in phthisis appear not to have been so extensively used, because of the satisfactory results obtained with the cabinet." With the cabinet it is possible to accomplish what you state to be so desirable. By means of a double valve it is very easy to modify the pressure, so that it is negative during inspiration and positive during expiration. Dr. Westbrook and myself have been accustomed to use the Evans' spray apparatus in connection with the cabinet. This vapor-like spray is delivered into the breathing-tube, and expiratory effort is instantly indicated by a puff of spray out of this tube. With the hand on the lever, the pressure can be altered so that an inch of a column of mercury, in the intra-cabinet pressure, could be made with each of the respiratory acts, if it was thought desirable. The method is one we use frequently, and is spoken of as pneumatic differentiation.

Very truly yours,
A. H. BUCKMASTER, M.D.

163 CLINTON STREET, BROOKLYN.

VACCINE AND VARIOLA.—Dr. J. B. Buist has made an exhaustive investigation into the natural history of the vaccine and variolous contagium, embodying a large series of experiments and observations. The following are the more important of his conclusions: (1) Stored lymph undergoes acid fermentation unless preserved in the dry state. (2) Vaccine contagium can be isolated and cultivated apart from the animal body in both solid and liquid media. (3) The properties of pure dried yeast and diastase are very similar to those of the vaccine contagium. (4) Artificial and natural vaccine differ widely in potency and composition. (5) Natural vaccine, containing a preponderance of embryonic germs, gives rise to perfect local results, while the presence of mature germs causes violent local, and probably constitutional, results; lastly, (6) standard vaccine lymph, propagated as at present, is the best and most convenient material for vaccination. The book is copiously and beautifully illustrated, and may pave the way to further researches on the bacteriological culture of vaccine material.

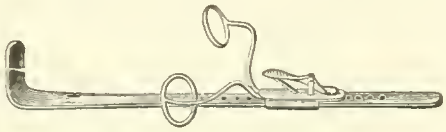
New Instruments.

A SELF-RETAINING UVULA- AND PALATE-RETRACTOR.

By W. PEYER PORCHER, M.D.,

CHARLESTON, S. C.

This instrument, as will appear from the cut, is an ordinary palate-hook, upon the stem of which a slide-attachment has been added. From the front of this slide project two arms, which end in two medium-sized rings, and at its rear is an automatic spring-catch which penetrates the perforated stem at short intervals. When in position the two rings on the arms rest on either side of the nose, just above the alveolar processes, and are easily retained there by the counter-pressure of the retracted palate. It is light in construction, weighing but four hundred and forty-five grains, easily adjusted, and releases both hands for operation and the management of the mirror. At my request, Dr. J. Allen Miles, D.D.S., made the original model, as I found the old method of operating—by means of pieces of tape or cord passed through the nostrils and clamped or tied over the upper lip—so disagreeable to the patient, as well as difficult and awkward to the operator. It lifts up and retracts the palate with perfect firmness and security. In fact, so entirely efficient has it proved, that with it operations can be performed in the posterior nasal space as easily as in any other region. It has been highly commended by distinguished laryngologists, as well as by general practitioners.



The following letter was received from Dr. J. Solis Cohen, to whom I submitted a model of the instrument, and he has kindly consented to its publication.

1421 Walnut Street, Philadelphia, September 28, 1887.

My dear Doctor: To-day is the first opportunity I have had to give the instrument you forwarded to me a trial. I was very successful in using it, and without cocaine. I like it very much indeed, and think it is the simplest mechanism I have seen.

Yours very truly,
J. Solis-Cohen, per F.

A NEW FORM OF PESSARY FOR THE RELIEF OF PROLAPSUS UTERI.

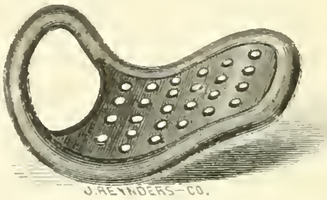
By CAROLINE R. CONKEY, M.D.,

WATERTOWN, N. Y.

No physician doubts for a moment the utility of surgical treatment for the relief of prolapse of the uterus, but it is not always possible to obtain the patient's consent to its use. Mechanical treatment is often the only sort the patient is willing to undergo, and a suggestion of surgical interference from the doctor will often cause his dismissal.

In consequence of this prejudice, I have in many different cases attempted to replace and keep in position a uterus prolapsed to the third degree by using the different supporters made for this purpose. A pessary which has to be worn for life should be free from the objection common to all pessaries with an external support, that they are a constant and increasing source of irritation to the parts. I have therefore discarded, in the treatment of such cases, those pessaries with an external support; and my best results were, from the first, obtained with a bow-pessary made by John Reynders for the treatment of retroversion, carefully fitted to meet the requirements of the case.

This would do the work satisfactorily, if it were not for the accompanying prolapsed condition of the vaginal walls, which, after the replacement of the uterus, bag down between the arms and at the sides of the pessary, and finally either push the pessary out, or cause the patient discomfort nearly equal to that of the original complaint.



In order to remedy this disadvantage in the use of the bow-pessary, I contrived one similar in curve, but of solid rubber from side to side, exclusive of the part which goes behind the cervix, the solid portion being perforated with holes to diminish the weight and allow free drainage. I introduced this five months ago in a case of prolapse, and it has since been worn constantly with the most perfect comfort. In the only other case I have had in the meantime I used the same pessary, with the same satisfactory result, and I feel justified in recommending it to the use of the profession because in these cases I had tried all other means unsuccessfully, and because I found the indications which other pessaries failed to meet supplied in this.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 1 *to January* 7, 1888.

Cleary, P. J. A., Major and Surgeon. Granted leave of absence for one month. S. O. 138, Department of Arizona, December 25, 1887.

Ebert, R. G., Captain and Assistant Surgeon. Ordered from Fort Custer, Mont., to Fort Pembina, D. T. S. O. 301, A. G. O., December 30, 1887.

Appel, A. H., Captain and Assistant Surgeon. Granted leave of absence for twenty days. S. O. 1, Department of Missouri, January 3, 1888.

Ewing, C. B., First Lieutenant and Assistant Surgeon. Granted leave of absence for one month. S. O. 137, Department of Missouri, December 27, 1887.

Banister, William B., First Lieutenant and Assistant Surgeon. Ordered from Fort Lowell, Ariz., to Fort Wingate, N. M. S. O. 3, A. G. O., January 5, 1888.

Animal and Vegetable Diets Compared.—Dr. Baftalovski having secured the intelligent co-operation of four medical friends, proceeded to diet them and examine their secretions, in order to obtain information as to the different effects produced by various classes of food on the human organism. With purely animal diet the mean assimilation was ninety-five per cent., and the nitrogenous metabolism 108.6 per cent.; the extractive matters in the urine being more than when the diet was exclusively vegetable. With vegetable diet the assimilation was 42.5 per cent., the nitrogenous metabolism much less than with animal food, and the extractive matter four times as great as with a mixed diet. With a mixed animal and vegetable diet the assimilation was nearly as high as with the exclusively animal food, being 92.4 per cent.; but the metabolism was considerably less than with animal, but more than with vegetable, food.—*The Lancet.*

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 7, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	5
Scarlet fever	148	23
Cerebro-spinal meningitis	1	1
Measles	42	5
Diphtheria	181	56
Small-pox	3	0
Yellow fever	0	0
Cholera	0	0

FOR THE SUPPORT OF PHYSICIANS.—A sum of fifty thousand marks has been granted by the Saxon Government, in its new budget, toward the support of physicians who settle in the poorer districts of Saxony. A less sum is also to be granted toward the maintenance of resident veterinary surgeons.

ETHEREAL TINCTURE OF PHOSPHORUS IN THE PNEUMONIA OF INFANTS.—Dr. Rochas Faria, of Brazil, claims to have obtained excellent results from the use of an ethereal solution of phosphorus in infantile pneumonia when asphyxia is threatening. He gives a teaspoonful every hour of a mixture of eight drops of the ethereal tincture of phosphorus in four ounces of cinnamon-water and sirup. The cyanosis, he says, disappears under this treatment within twenty-four hours, the cough becomes easier, and the general condition rapidly improves. The same treatment, Dr. Faria adds, seems to give good results in senile broncho-pneumonia.—*Revue Génerale de Clinique et de Thérapeutique.*

A CURE FOR LYING.—Dr. Voisin relates the case of a girl, eleven years of age, who was a most inveterate and persistent liar, and whom he cured completely of this reprehensible habit by means of hypnotism. Here is a grand field of usefulness opened before this young science.

A CONGRESS FOR THE STUDY OF TUBERCULOSIS.—A call has been issued for a congress of physicians and veterinary surgeons, having for its object the study of tuberculosis in man and the lower animals. The meetings will be held in Paris, on July 25 to 31, 1888. All physicians and veterinary surgeons, from whatever country, may become members of the congress on the payment ot ten francs. The official language will be French. The president of the committee of organization is M. Chaveau, and the secretary-general M. L. H. Petit.

PUTREFACTION AND INFECTIOUS DISEASES.—At the recent German Congress of Natural Sciences, Dr. Hueppe delivered an address on this topic (*The British Medical Journal*). Pringle and Frank in the eighteenth century declared that "putrid fevers" were due to putrefactions going on external to the organism, and Pringle recognized a relationship between epidemics of such fevers and the depth of the water-level below the surface of the ground. Previously to this, if we except Frascatori in the Middle Ages, scarcely any attention had been directed to external influences from the time of Hippocrates, and, after him, of Diodorus. As for putrefaction itself, the idea that this was caused by the growth of low organisms was never even broached till the present century. The old view was that the term "life" connoted the absence of putrefaction, apparently because the healthy body resisted invasion by pathogenic germs. Against this view Henle strongly set himself, taking for his basis the investigations of Schwann and Cagniard Latour as regards *infusoria*, and those of Bassi and Audouin on infectious diseases. In fact, Henle's ideas were very advanced, for he thought that infective diseases were due to germs starting from without, and that these germs were due to putrefaction. Further, Henle ventured to argue that "it depends on special conditions wnat kinds of *infusoria* and plants develop, and the different kinds are not equally inimical to health." The natural development from this is that the living tissues resist pathogenic organisms during health, but that if this resistance be overcome the invading organisms develop, and decomposition goes on within the body, much as in external putrefaction, only modified in form and derivation by the tissues, and this conclusion has been confirmed by the investigations into the chemistry of bacteria by Nencki, Gautier, Selmi, and, above all, Brieger. Pettenkofer made a further step forward, for he divided the still hypothetical "infectious material" into entogenous and ectogenous. But his conceptions were too absolute. Pettenkofer held that the germs of infectious diseases were discharges from the body in an unfit, ineffective condition, and that only after a process of ripening outside the body could they again produce the original disease. We know that the case is otherwise, that, as a rule, such germs are most effective when discharged from the body, and that they do not acquire increased vigor from contact with mother earth, as certain heroes of old did, but rather tend to lose vigor and gradually perish. Nevertheless, we owe Pettenkofer a great debt for so early recognizing that many disease-organisms do go through certain stages of development outside the body—in some cases, as in the spore-formation of anthrax bacilli, only outside it. Our knowledge now begins to be more precise regarding disease-germs. Pasteur definitely established the fact that putrefaction and fermentation processes are due to the growth of the respective organisms. Next, as regards disease, F. Cohn put all the disease-producing organisms in one class apart. Davaine had already shown that anthrax bacilli were excitant of ordinary septicæmia. Koch taught us the isolation and cultivation of bacteria, and Panum showed that putrid fluids may act as poisons even when no organisms are present. By this last step, previous pathological conceptions were etiologically fixed, and "putrid intoxications" due to poisons elaborated by bacteria were distinguished from the diseases caused by the entry and development of the specific bacteria themselves within the system. It was afterward shown that the system could be intoxicated from within by bacteria. To go back for a moment to the beginning of our own century, Majendie's researches deserve mention here, because he showed that certain substances were developed in septicæmias (in animals), which, when transferred to other animals, set up a similar disease. Semmelweiss, "the well-known gifted founder of aseptic surgery," extended this observation to man, and by his success in the treatment of puerperal fever was the first to establish a beneficent prophylactic therapeutical system. It will be seen that many problems regarding disease-producing organisms were only rendered possible of solution through the attempts of Pasteur, Hallier, and Klebs—acting with ideas contrary to those of Cohn, who placed all such organisms in one class—to cultivate and separate the different kinds of bacteria, attempts which Koch carried on to a glorious fruition. It is now known as regards a whole series of pathogenic bacteria that they possess a saprophytic stage, and that their "parasitism" in the human body is not at all necessary to their existence as species, but only accidental, a view which Henle and Pettenkofer from epidemiological considerations had already strenuously advocated. Such is the substance of the historical sketch given in this remarkable address, the rest of which deals with recent systems of classification of bacteria, and of the diseases arising from them, a large part being devoted to the various organs of the body, as they are mainly involved in different diseases, especially cholera nostras, and cholera Asiatica. As regards this part, we have no space for further representations of the author's views, but some concluding remarks may be given as reflecting creditably on hygienic medicine in this country: "As long as a circulation of material goes on, as long as putrefactive processes are necessary as affording an intermediate stage between animal and plant life, so long will micro organisms exist, adapted for the destruction of albumen, or, by an alteration of the processes, for albumen-putrefaction. And so long as this occurs, organisms will continue to exist which, owing to this adaptation, are capable of setting up disease in the human body. We can never altogether conquer putrefaction—*tamen usque recurret.* But if—to quote Lord Palmerston—we regard dirt as only something in the wrong place, and regard putrefactive processes in our immediate neighborhood as in the wrong place, because uncontrollable and dangerous, we are then able to fight with those processes and their dangers without sacrificing the necessary processes for the circulation of material, together with their advantages. . . . Let these processes go on in the *humus* of the garden and the field, the meadow and the forest, where proper adaptations for plant life exist. . . . I adopt the English conception, which regards cleanliness—not a mere façade-cleanliness, though—as health itself, and the best means of fighting against infectious diseases."

Sparteine in Cardiac Affections.—Dr. Maslovsky formulates the following conclusions from his experiments made to determine the efficacy of sparteine in the treatment of heart disease (*Russkaya Meditsina*, No. xiii., 1887): 1. In moderate doses sparteine stimulates the heart, renders the pulse more full and reduces slightly the number of its beats. 2. Its action is rapid. 3. The heart's action does not become perfectly regular under the use of the drug. 4. The quantity of urine excreted is somewhat increased. 5. The drug possesses no cumulative action. The dose is from one-fifth to two-fifths grain per day.

A Safety Coffin.—An inventive German has devised a coffin for the convenience of those who have a dread of being buried alive. It is provided with a valve by means of which fresh air is admitted in quantity sufficient to support life, and there is an arrangement of wires by means of which the least movement of the body sets an electric bell to ringing.

Sir Andrew Clarke's Treatment for Anæmia and Chlorosis (Fecal Anæmia).—On first waking in the morning sip a quarter of a pint of cold water. On rising take a tepid sponge-bath, dry quickly, and follow with a brisk towelling. Clothe warmly and loosely; see that there is no constriction of the body or of the limbs. Have four simple but liberal meals daily, arranged after this fashion: *Breakfast*, 8 to 9.—Wholemeal bread and butter with one or two eggs, or some broiled fresh fish, or the wing of a cold chicken or pheasant, and toward the close of the meal half a pint of equal parts of milk and tea, not infused longer than five minutes. *Lunch* or *Dinner*, 1 to 2.—Fresh, tenderly dressed meat, bread, potato, well-boiled green vegetable, and any sort of simple farinaceous pudding, or of cooked fruit, preferably apple. Drink one glass of Burgundy, alone or in half a tumblerful of water. *Tea*, from 4 to 5.—Wholemeal bread and butter, with a cup of equal parts of tea and milk. *Dinner* or *Supper*, from 7 to 8.—This should resemble the mid-day meal, but should be less in quantity. Nothing is to be taken after this meal, nothing between meals, and nothing but what is here set down. Walk at the least half an hour twice daily, and as much more as strength and convenience will permit. Retire to bed about 10, and repeat the sponging and towelling. See that your bedroom is cool and well ventilated. Lead a simple, regular, active, occupied, purposive life, and do not notice or distrust yourself. With such instructions, modified according to individual peculiarities, I prescribe a ferruginous cathartic to be taken twice a day, about 11 A.M. and 6 P.M. Usually it is an acid mixture, somewhat as follows: ℞. Ferri sulphatis, gr. xxiv. ad gr. xxx.; magnes. sulph., ʒ vj.; acid. sulph. arom., ʒ j.; tinct. zingiberis, ʒ ij., vel syrupi zingiberis, ʒ vj.; inf. gent. co. vel quassiæ, ʒ viij. Fiat Mist. Sig.: One-sixth part twice daily, about 11 A.M. and 6 P.M. Occasionally this acid mixture produces sickness, dries the skin, and is otherwise ill-borne. In such circumstances I prescribe an alkaline cathartic mixture: ℞. Ferri sulphat., gr. xxiv. ad gr. xxx.; sodii bicarbonat., ʒ ij.; sodii sulphat., ʒ vj.; tinct. zingiberis, ʒ ij.; spt. chlorof., ʒ j.; infus. quassiæ, ℥ viij. Fiat Mist. Sig.: One-sixth part twice daily, about 11 A.M. and 6 P.M.

Discoloration of the Skin by Nitrate of Silver applied to the throat. Dr. J. Walters writes to the *British Medical Journal:* "A well-marked case of argyriasis came under my observation, some years ago, in the person of a woman sixty or seventy years of age, who, many years previously, had been supplied with a solution of nitrate of silver to apply to her throat."

The External Use of Quebracho.—The fluid extract of quebracho is recommended as an application to wounds of all sorts, but especially to the ulcers resulting from burns and frostbites. It forms a firm coating over the ulcer, under which cicatrization proceeds rapidly as under a scab. The application causes a little smarting at first, but this is slight and soon passes away.

Commodore Perry's Views of Scurvy.—In his "Life of Commodore M. C. Perry," W. E. Griffis says: Matthew Perry was among the first to discover the underlying cause of the sailor's malady—sea-scurvy. He believed it to be primarily due to malnutrition. He found the soil in which the disease grew was a compost of bad water, alcoholism, exposure, too exclusively salt diet, lack of vegetables, of ventilation, and of cleanliness on ship. The canning epoch inaugurated later by Americans, who, it is said got their notions from air-tight fruit-jars dug up from Pompeii, had not yet dawned, but Perry already put faith in succulents. Though not yet familar with the marvellous power of the onion, and the juice of limes, he endeavored at all times to secure supplies of sauer-kraut, cabbages, radishes, and fruits rich in acids and subacids. He was emulous of the success of Captains Cook and Parry who had succeeded so well in their voyages. He knew that in war more men perished by disease than in battle. He lived to see the day when a ship was made a more healthy dwelling place than the average house, and when, through perfected dietetic knowledge, and the skill of the preserver and hermetic sealer, sea-scurvy became so rare that a naval surgeon might pass a lifetime without meeting a case save in a hospital.

An International Exhibition is to be held in Brussels from May 3 to November 3, 1888. In addition to the exposition, there is to be a convention for the purpose of demonstrating how each article on exhibition can be best and most cheaply manufactured.

The Treatment of Sciatica.—Dr. N. O. Parks, of Ashton, R. I., writes: "In The Medical Record of November 12, 1887, is mentioned the treatment for sciatica, recommended by Dr. Burggraeve, of a local application of iodine, collodion, and ammonia water. I find this mixture will not work, the gun-cotton being precipitated from the collodion."

The Sign of Jove.—Dr. Napier, and other physicians of the seventeenth century, said that ℞ stood for *Responsum Raphaelis* (Reply of Raphael), and was used because the angel Raphael was supposed to impart prescriptions. This suggestion is, however, a latter-day legend, which receives no credence.

ON SOME POINTS IN THE SURGERY OF THE URINARY ORGANS.[1]

BY REGINALD HARRISON, F.R.C.S.,

SURGEON TO THE LIVERPOOL ROYAL INFIRMARY, AND LECTURER ON CLINICAL SURGERY IN THE VICTORIA UNIVERSITY.

LECTURE II.

THE PATHOLOGY OF THE ENLARGED PROSTATE VIEWED IN RESPECT TO ITS CAUSATION AND PREVENTION, AND THE TREATMENT OF SOME COMPLICATIONS ARISING OUT OF IT.

I PURPOSE this evening speaking of the pathology of the prostate, relative to some points in connection with the prevention and treatment of certain disorders arising out of it when it becomes hypertrophied. The causes of hypertrophy of the prostate have formed the subject of much careful observation, and I feel some hesitation in again referring to them. Still, on the other hand, though my views may not prove generally acceptable, I am inclined to think that a narrative of the observations upon which they are to a large extent based may serve a useful purpose in indicating lines of thought which may result, sooner or later, through the investigations of others, in clearing up doubtful passages in the physiology and pathology of this part. In the first place, I shall speak of the prostate as forming the retentive apparatus of the male bladder, under whose influence the urine is collected and held, irrespective of any glandular function which, by the nature of other structures it may contain, it is capable of exercising. And I think it will not be difficult to substantiate the proposition that, in the human species at all events, this part may with greater propriety be designated *the prostate muscle*, rather than *the prostate gland;* for whatever function it may exercise intermittingly, relative to the process of generation in its latter sense, seems to be subservient to the physical part it is continuously playing as a portion of the retentive apparatus. In support of such a view I would draw attention to Mr. Ellis' important paper[2] "On the Muscular Arrangements of the Genito-Urinary Apparatus," wherein is remarked: "I would propose the name *orbicularis vel sphincter urethræ* for both the prostate and the prolongation around the membranous urethra, while I would confine the old term 'prostate' (without the word gland) to the thickened and more powerful part near the neck of the bladder. This orbicularis may be considered as only an advanced portion of the circular layer of the bladder, though it must have the power of acting independently of the vesical fibres." But if its muscularity is admitted, we must conclude that it, for the most part, exercises its function in conjunction with the bladder, in the form of a hollow muscle, for it would be against the nature of things for it permanently to exist in the shrivelled and contracted state it presents after death. We have been too much accustomed to regard the prostate from its post-mortem aspect; that is to say, as a mass of muscle of the size and form of a chestnut, in which is contained some secreting tissue. For concluding that it thus exists during life, I believe there are no substantial grounds, as it seems to me that under no circumstances, save the rare and momentary one when the bladder is absolutely empty, does it present such an appearance. On the contrary, the muscular fibres are spread out like a funnel, with the apex downward, so as to form a strong muscular support for the bladder and its varying amount of contents, the degree of expansion being naturally relative to what the viscus may contain. Hence the action of the prostate may be said to be just as continuous as that of the heart. In reference to this important point, it will be necessary that I should furnish some reasons for such a conclusion.

In the first place, the clinical examination of a healthy person, with varying amounts of urine in his bladder, affords no evidence that the prostate presents the contracted appearance we are accustomed to see; on the contrary, when the finger is introduced into the rectum, in the natural condition, the parts are felt to be disposed in the manner I have indicated, and providing a muscular floor for the bladder and its varying amount of contents.

But the retentive function of the prostate is more strikingly shown when we proceed to what I would speak of as actual demonstration. And for this purpose we have only to observe what follows in connection with certain surgical operations on these parts with which most of us are familiar. Incisions may be made into the male urethra, in any part of its course, as far as that point which we are accustomed to call the apex of the prostate, without any incontinence of urine following. I have seen cases of lithotomy by the median operation retain full control over the bladder during the whole period of their convalescence, in spite of the dilatation to which the prostate has been subjected by the introduction of the finger and the extraction of the stone. And this remark applies equally to cases of external urethrotomy.

When, however, the knife impinges to any appreciable extent upon the prostate, as in the lateral operation for stone and the modified median operation which I have recently drawn attention to where the prostate is divided, from that moment incontinence takes place; the patient has no command over his urine; he can neither collect nor expel it, and in this condition he remains until the healing process has made considerable advance. We have here striking evidence not only as to the habitual function of the prostate relative to the contents of the bladder, but that the action of the part must be unceasing in its character, subject to the circumstances under which it has to distribute its force over the area it supports or brings into action. How completely the prostate forms the lower section of the bladder was demonstrated to me in a striking manner only a few weeks ago, and in a way that I had not previously noted. It was a case of lateral lithotomy in a young man, where, ten days after the operation, there was some free hemorrhage. As the bleeding did not proceed from any part of the perineal wound, I had the patient put under ether on the operating-table, and, suspecting where the bleeding came from, I introduced the nozzle of a Higginson's syringe into the orifice of the urethra, expecting that the fluid would run out of the open urethra; this it certainly did, but not until it had first entered the bladder, out of which the fluid escaped, together with some old clots which had evidently collected in the viscus, just as water would do out of the side of a cask in which a hole had been made. This I was able to see, as the wound was held open with retractors under a strong light. In addition, however, to testimony of this kind, I am convinced, from a careful examination of the prostate, both before and after operations on this part, where the introduction of the finger into the bladder formed a detail of the proceeding, that the more usual condition of the healthy prostate is one of relaxation, and not of contraction, as we are accustomed to see when death has taken place.

[1] The Lettsomian Lectures, delivered before the Medical Society of London, January, 1888.

[2] Royal Med. Chir. Trans., vol. xxii.

But further, when there are no such physical functions to perform relative to the contents of the bladder, the prostate, as a muscle, so far as I have been able to ascertain, only exists in a rudimentary form. I refer to those distressing abnormalities known as extroversion of the bladder, where, from the fissured nature of the structures, there is no receptacle for the urine which escapes from the ureters as it is excreted. Here, though the sexual sense may be normal, there is, from the nature of the parts, no necessity for any provision being made for the collection and retention of what the kidneys secrete. I have not been able to discover, though I have taken considerable pains to do so, that in these abnormalities hypertrophy of the prostate has ever been noticed. This seems to me to be a point of some significance in connection with what has been already urged. But though in an argument of this kind I would prefer to substantiate my position from positive evidence rather than by a deduction from the negative, I cannot help remarking that, if the office of the prostate was solely in relation to the sexual act, the pathology of the part would tend to indicate this more than I believe it does. It is not very uncommon to meet in practice with cases of acute suppuration commencing in the follicles of this part, where one would think that irreparable damage must have been done, and yet we have evidence to show that the individual has not necessarily been unsexed by this process. Nor can I assert, though the opportunity for doing so has now for some years been abundantly provided me in my operations, involving varying degrees of mutilating the prostate, that I ever extinguished the procreative powers.

In the next place, I would point out that adult man seems to require some special provision, such as the prostate affords, for the purpose I have just indicated, by reason of the exceptional degree of pressure to which the most dependent portion of his bladder is constantly subjected. And in making use of the words, "exceptional degree of pressure," I do so in contradistinction to what is found, so far as I have been able to observe, not only in the animal kingdom, but in other varieties of the human species which are not in exact correspondence with the type I have taken. As demand and supply in the disposition of muscular tissue are proportioned, it seemed to me that we had hitherto failed fully to recognize and appreciate all the circumstances which rendered it necessary that the adult male bladder should, as I have already pointed out, be provided with a muscular apparatus of considerable strength at its most dependent point. But in what respects, it may fairly be asked, does the adult male bladder differ from other varieties of its own species, and from those animals which in their higher organization more closely approach it? I maintain that in man the perpendicular axis, of what I would speak of as urine pressure, falls directly upon the outlet of the bladder, whereas in the female, not only are there other means of supplying muscular support to the base of the bladder, but, in consequence of the difference in the pelvic organs, a considerable portion of the weight of the viscus, especially in its more extreme degrees of distention, is borne by the pubic portion of the pelvis. Further, allowance must be made in the female sex for no provision being necessary for seminal ejaculation, in which function the muscular fibres of the prostate undoubtedly play an important but occasional part. In the higher mammalia, excepting, perhaps, in the case of dogs, the prostate is not so largely developed as in man. In reference to this point, Mr. Bland Sutton kindly informs me that, although he has conducted many thousand post-mortems, yet, except in the doubtful case of dogs, he has never seen an enlarged prostate, at all events such a one as would cause obstruction to the flow of urine. In animals, it will be observed that the perpendicular axis of urine pressure, when the bladder is tolerably full, does not fall, as in man, on the outlet, but on the parts which support the bladder according to its varying degree of distention. In the dog, it seems to me not improbable that the exceptional degree of prostatic development is related to the somewhat peculiar condition under which, in this animal, micturition is performed. As my opportunities of examining the urinary apparatus in the lower animals have been few, I feel much hesitation in making reference to any observations I may have rather casually made, so far as they related to the point under discussion. It, however, appeared to me that where the habits of the animal, as observed in some apes and marsupials, necessitated the frequent adoption of an erect position, that the males had a much greater development of the prostate muscularly than was usually found in other kinds of quadrupeds. I regret very much that we have not at our disposal more abundant means for referring to dissections illustrative of the comparative anatomy of the body. I am sure they would prove of much assistance in investigations of this kind having relation to normal and morbid human anatomy. But apart from this, if time permitted, it would not be difficult to adduce further evidence to show that in man the collection and storage of urine, if I may make use of such a term, implies a degree of muscular support to the most dependent portion of the viscus for which no such complete provision has to be made under any other condition of life I am acquainted with. I should not, however, feel at all surprised if, when the missing link is discovered, he is found paying the penalty for his assumption of the erect posture by developing in some degree an enlarged prostate.

But to proceed. If the prostate represents the chief means of retention and support for the contents of the male bladder, is it necessary to pursue the argument for the purpose of explaining why it becomes hypertrophied? Does not one follow upon the other? Are not the circumstances of individual life sufficient to explain why it happens to one person and not to another?

Many of the facts connected with the natural history of hypertrophy which have been collected for us, or with which, in our daily practice, we are familiar, seem to me to support the view I have taken relative to the function of the part. In the first place, it is not met with during those periods of life which are most remarkable for muscular activity and development; on the contrary, it is called into existence where, pathologically speaking, quantity seems to supplement deficiencies in quality.

But, as with similar changes in other parts of the body, so may prostatic hypertrophy be shown to be exactly compensatory; while in others, by an excess of the process, it may be proved to be detrimental. And in reference to this point I would remark, that we have been too much accustomed to regard prostatic hypertrophy as necessarily a morbid and hurtful process. To such a conclusion I think exception may be taken on substantial grounds. It is stated by Sir Henry Thompson that actual hypertrophy of the prostate exists in about thirty-four per cent. of men at and above sixty years of age; that it produces manifest symptoms in about fifteen or sixteen per cent. From this it would appear that the larger proportion of persons are not injuriously affected by the change, a circumstance which seems to suggest that the majority of persons with large prostates are in some way or other benefited by them; and this deduction is considerably borne out by every-day experience. I am disposed to think, from my own examinations, that the frequency of some degree of prostatic hypertrophy is thus rather under- than over-estimated. Though it is not easy to form an absolutely correct estimate of the size of these parts, relative to standard measurements, by rectal examination, my conclusion is that a far greater number of males over sixty years of age have some enlargement of the prostate, and are never in any way conscious of the alteration, than we should conclude from the figures I have just referred to. How frequently, for instance, when we are examining elderly persons, say for some disorder of the rectum, we make the discovery that their prostates are enlarged, though they have no reason to be conscious of this change. I can, at this moment, recall many instances of this in my own practice, where the persons are, in every sense of the word, in the enjoyment of the most perfect health, with an entire absence of any urinary ailment. Quite recently I was asked to examine a gentleman who, in the course of an acute bronchitis, had retention of urine for the first time in his life. This patient had an enormous prostate, which must have been in course of formation for several years. Surely, under these circumstances, in the first instance the hypertrophic change must have been called into existence for a distinctly conservative object, and had been merely disarranged by the violence of the cough from which he was suffering.

But though prostatic hypertrophy is, as I have shown, in the greater number of instances, more or less compensatory, it may, as in others, be in excess of what is required, and thus prove detrimental. In the latter category, reference, no doubt, will occur to us of those examples where the prostatic mass is made up of projections having a somewhat lobulated or nipple-like form, where the degree of irritation and obstruction excited is often very considerable, and apparently out of proportion with the cause. These I would speak of as being the structural upheavings of a frequently contracting muscular ring. In a muscle or part undergoing hypertrophic growth, and where the process is prompted by circumstances which are obviously liable to some degree of variation, tissue-production may be excessive or become unnecessary. Such excess would naturally tend, under the contraction of the part, not only to protrude itself where the resistance was least, but to assume a more lowly organized form than that which in the first instance was developed. In this way, I believe, these masses of more or less degenerated prostate tissue are formed, which subsequently cause so much vesical irritation and irritability. And this observation, whether a large prostate still remains almost entirely muscular, or has become largely converted into fibrous tissue, has an important bearing in practice in those cases where we have to express an opinion in reference to the probabilities as to whether the use of the catheter will be a temporary or a permanent expedient. For where there is evidence to the touch that fibrous tissue predominates largely over the muscular, the use of the catheter is generally perpetual; while, on the other hand, when the prostate is found soft and yielding to the touch, as when it remains muscular, a complete restoration of function may be anticipated. Thus, then, may the resistance which is constantly going on in the most dependent portion of the bladder, against that downward pressure which is exercised by the collection and retention of urine in the bladder, prove the common cause of its hypertrophy.

But this is not the only condition under which hypertrophy involving the lower section of the bladder can be studied.

In the examination of the bladder, both after death and in the course of surgical operations, it is impossible not to be struck with the altered relations which frequently exist between the body of the viscus and its neck or outlet. In early adult life the bladder may be regarded as an abdominal rather than a pelvic organ; as years advance it gradually sinks within the pelvis; while still later on, it will often be found to have become further depressed within the pelvic cavity. In this way I have seen a prominence given to the floor of the prostate which was really due, not to the development of more prostate tissue, but to the depression or partial prolapse of the posterior wall of the bladder. This artificial condition of obstruction I have endeavored to show, in some instances, not only precedes prostatic obstruction, but, further, is followed by the development of a strong muscular buttress between the orifice of the ureters, which in many instances leads to the obstruction of what otherwise would prove, by the sinking of the posterior wall of the bladder, an inconvenient pouch. Thus hypertrophy of the prostate and the adjacent part may not only be due to the natural resistance of urine pressure, but also may be called into existence for the evident purpose of supplementing a structural defect of more or less accidental origin.

It is impossible to observe the function of micturition in the child and the adult without recognizing that in the two conditions there are wide differences in the influence that the will exercises upon the merely mechanical act. In the child the process almost approaches the involuntary, the calls of nature are impulsive, and must be obeyed without hesitation. This may be illustrated in a variety of ways, both in health as well as in disease. In adult man this is to a large extent changed, as we find the process becomes much more subservient to the will than perhaps at first sight we should feel disposed to admit. That there is a wide difference in our respective powers of continence in this respect I am willing to admit. In some individuals the function of micturition seems in health but very slightly removed from a purely voluntary act. Let me illustrate what I mean. A medical man, closely approaching seventy years of age, asked me to examine his rectum for some slight ailment. In doing so I found that he had a very large, soft prostate. I mentioned this to him, when he remarked: "I could hardly believe it, as I have always had such excellent water-works. I have been in the habit of not passing urine for eight or ten hours." Here, then, is an illustration of a man who submits his bladder to the same degree of urine pressure at seventy as he did when he was twenty-seven. Again, a captain of one of our ocean steamers, in consulting me in reference to some urinary disorder clearly connected with a large prostate, in comparing his present with his past powers of retaining urine, remarked that, in consequence of remaining on the bridge of his steamer for long periods of time, particularly in thick weather, without leaving it to pass water, he had acquired a power of retention which had gradually become constant. It is remarkable that nature had thus substituted quantity for quality, and had made provision against the effects of a muscular strain which could not have been inconsiderable. We might from our daily practice multiply examples of this kind where persons, so far as was known, were not deriving anything but good from that excess of muscular tissue which we are accustomed to speak ot as the prostate gland. If we admit that the muscular fibres of which the prostate is so largely composed exercise the function I have urged relating to the contents of the bladder, I do not think we can be at a loss to understand how they become hypertrophied.

Let me, however, not be understood as implying that in the human species the prostate has no relation with the sexual act. Evidence is not wanting to show that, as a muscle, as well as by reason of its glandular element, it exercises purely physical functions relative to this important but casual function, independently of the continuous action I have laid stress upon in relation to micturition. The less important function of the glandular portion of the prostate has been, I believe, correctly described by Dr. Handfield Jones[1] in the following words: "Its part in the generative function is probably not to prepare any essential element of the fecundating fluid, but merely an appropriate viscid material, involved in which the seminal animalcules may be more securely transported on their destined route."

---

[1] The London Med. Gazette, vol. v., 1847

Passing to some considerations relative to the prevention of prostatic hypertrophy, and the complications arising out of it, I would observe that more care should be systematically taken to preserve the muscular power of the bladder, and to aid it artificially when the necessity obviously arises. If a man goes on using his bladder as he would a water-bottle, from adolescence to old age, he must not be surprised if nature prevents it breaking down entirely by the process I have described. The timely use of the catheter has often, I am sure, provided the means for warding off changes which unfortunately do not always cease when they have become precisely compensatory. Nor is there anything exceptional in this, for as age advances we recognize the importance, and make use of artificial assistance in a variety of ways which I need hardly particularize. In the clinical history of most cases of hypertrophy of the prostate, we can generally trace a period when a weakness of the viscus indicated itself by a frequency in action which was subsequently corrected by an overgrowth in the part. But, unfortunately, the process of hypertrophy, as observed in the prostate, is not always precisely compensatory, it is not infrequently in excess. In by far the larger proportion of these instances the individuals are able not only to keep themselves comfortable by the use of the catheter, but I question very much whether their lives are in any way shortened by the continued inconvenience they have thus to submit to. Many of us could record some remarkable example of longevity under these circumstances. But making due allowance for this class of cases, there are others whose lives, in spite of careful and efficient catheterism, are rendered miserable and useless by what they suffer in this way. For no sooner does urine collect in their bladders to any appreciable extent than they require to get rid of it. Many expedients have been resorted to, both in the way of drugs and operative procedures, for the permanent relief of this condition, about which it would be impossible for me to speak in detail. Let me, however, refer to a case [1] which I reported some years ago, where I tapped the bladder from the perineum through the enlarged prostate, quite independently of the course of the urethra, and where a cannula was retained in this position for two months with great comfort to the patient. He was a man about eighty years of age, and had suffered much from almost all the complications that an enlarged prostate is capable of giving rise to. But the future of the case was perhaps still more interesting, for he completely recovered, and lived for several years, and in this I include the acquisition of the natural and unaided use of his bladder. Further, the explanation of this was found in the fact that during the time the cannula was retained in his bladder his prostate underwent a gradual diminution in size, which was noticed by all who had the opportunity of watching and examining him. His condition prior and subsequent to the operation proved a most remarkable and instructive contrast. I may add that this process has been repeated not only by myself, but by others, with very satisfactory results, and this tends in no slight measure to substantiate the views I have already advanced relative to the pathology of the disorder. And in connection with puncture through the prostate, I would like to say a few words in reference to cases where relief has been afforded, under similar circumstances, by an incision through the part similar in many respects to what is adopted in lateral lithotomy. There can be no doubt that prostatotomy, which affords a free and incontinent escape for urine from the bladder, has proved of very great temporary and permanent service in this class of cases. At the meeting of the International Medical Congress at Copenhagen, in 1884, I took the opportunity of illustrating this method of treatment as an alternative in cases where the catheter was of no avail in affording relief. And I will again refer to this operation, as sufficient time has now elapsed to enable me fairly to judge of the results obtained. The kind of cases to which this treatment has been applied are those of difficult micturition, due to a large prostate, which are not adequately relieved by the use of the catheter. This class, therefore, includes instances where there is unusual difficulty in introducing the catheter; where bleeding almost always attends the use of this instrument; where the withdrawal of the urine is followed by no sense of relief; and where the bladder, by the constant presence within it of pus and tenacious mucus, is converted into little else than a chronic abscess through which urine percolates. These, as well as some other forms of prostatic disease which might be included, are practically unrelievable by the catheter, and soon terminate in a painful death. For the relief of such conditions various expedients for establishing a more or less permanent communication with the bladder, other than by the urethra, have been practised; namely, puncture above the pubes, by the rectum, and from the perineum, with the retention of a cannula or tube for the discharge of urine at these several points. Excellent in design as these proceedings are, they appeared to me to fall short in one important respect—in not dealing with the cause of the obstruction. Two of these measures are open to objection on the ground that the artificial canals are inconveniently placed as permanent vents, for it would seem desirable that the urethra should, as far as possible, be utilized, and the external opening for the escape of urine be dependent. On considering various plans of treatment which had been applied under the circumstances mentioned to the obstructing prostate, it appeared to me that by combining Cock's well-known and safe operation for opening the membranous urethra with Mercier's for dividing the prostatic bar from within the urethra, as will be presently noticed, it would be possible to obtain precision with an increased freedom from risk. Such an operation was suggested by the late Mr. Guthrie, but I cannot find that he ever tested it in practice. The want of anæsthetics probably interfered with the progress of this as well as of other departments in surgery. Apart, however, from the operative procedure, it appeared to me from some experience I have had in lithotomy and other operations on the parts constituting the neck of the adult male bladder, that the means which had been subsequently adopted for rendering the prostatic section thus made permanent, were very inadequate. Further, I had been impressed with the advantage that followed the employment of suitable bougies as dilators in cases where the prostate threatened to obstruct micturition.[1] Influenced by observations of this kind, I was led to attach considerable importance to the treatment immediately following section of the enlarged prostate, with the view of rendering it more permanent than had hitherto been attempted. The necessity for prostatotomy having been determined by the symptoms presented in each case, as well as by physical examination, I will describe briefly the operation and after-treatment employed. The former consists in opening the membranous urethra from the perineum on a guide, and introducing the finger within the prostatic urethra; the obstructing portion of the prostate is then divided a little to one side of the median line, partly by incision with a curved probe-pointed bistoury from within outward, and partly by divulsion with the finger, when the latter is feasible; a large drainage-tube is then introduced into the bladder. I attach considerable importance to the prolonged use of the drainage-apparatus, as the object is to render the section of the prostate not a temporary one, as after a lithotomy, when no such provision is made, but permanent. Hence, I am in the habit of retaining these tubes for six, eight, or ten weeks. If, after such periods, on removing the tube I find that a catheter can be made to enter the bladder easily along the natural route, or if, as it sometimes happens, urine forces its way, in spite of the drainage-tube, along the natural passage, I regard these as indications that the object in view has been obtained. The perineal wound is then allowed to close. Let me briefly illustrate this by the narration of one of my earliest cases.[1]

---

[1] British Medical Journal, December 24, 1881; April 8, 1882.

[1] The Prevention of Prostatic Obstruction. Churchill, London, 1881.

A man, aged sixty-three, came under my care in February, 1883, suffering from a large prostate, which was a constant source of irritation to him. The straining and forcing to urinate was but very slightly relieved by catheterism, and the only way he could get any sleep was by tying the instrument in, and this was generally followed by some cystitis. A fortnight after I saw him I opened the prostatic urethra by a median perineal incision, and incised the prostate laterally. In doing this I found that though the prostate was not very large, the orifice of the bladder was much obstructed by one of the nipple-like enlargements which are sometimes more effectual in rendering micturition difficult and catheterism uncertain than some larger masses. A drainage-tube was introduced and retained for four weeks, when it was removed, and the perineal opening allowed to heal. In this case so perfect was the drainage that the whole of the urine escaped by the apparatus, and the patient was kept absolutely dry throughout. He remained under treatment for two months after the operation. Three months after, he returned to report himself. There was a slight fistulous opening in the perineum at the lower angle of the wound, through which urine sometimes passed in drops during micturition. He could now hold his urine for several hours. Some slight enlargement of the prostate could be felt from the rectum, but this did not appear to have increased. A full-sized catheter was easily introduced without any hitch or obstruction in the prostatic urethra, or at the neck of the bladder, being felt. This patient was seen at intervals for two years after the operation, and remained perfectly well. He has since neglected to report himself. Though I advised him to pass a catheter for himself occasionally, I believe that he did not do so.

Taking the cases thus operated on, I have noted the following results: 1. The operation has merely afforded just such a temporary relief as the retention of a catheter or cannula would do as a drain, the condition of the patients, so far as recovery was concerned, being more or less hopeless at the time of operation. 2. The establishment of a permanent vent for the urine through the perineum. In two instances where this occurred the patients exchanged a life of misery for one of comparative comfort. The shorter route here proved most acceptable. 3. The substitution of easy for difficult catheterism. In one patient I thus operated on, though he had to use his catheter afterward so long as I heard of him, which was for over two years, he never had any difficulty in passing the instrument, and the bladder continued to be far more tolerant of urine than it had previously been. 4. The complete recovery of the patient, as I have just illustrated.

In discussions relative to the method of operation adopted, it has been pointed out that in some cases of this kind it must be absolutely impossible to explore the whole length of the prostatic urethra with the finger. This circumstance has never influenced me, or seriously interfered with my carrying out the object in view. I never met with a prostate of such a size or shape as to prevent a staff or guide being passed into the bladder, and where a director will go a knife may safely follow.

But to proceed. Though a more or less permanent vent or opening for the urine, either above or below the pubes, may prove of value in some instances of urethral obstruction due to prostatic hypertrophy, where ordinary catheterism is useless so far as the amount of relief that is afforded, it is not applicable to all cases of this kind. For we must remember that in the former class of cases it is merely a matter of urethral obstruction that we have to deal with, while in others the symptoms are for the most part due to the irritation that is provoked in the bladder by the protruding masses of more or less degenerated prostatic tissue. The one is to the other, as well as to the bladder, as urethral stricture is to vesical calculus. The examination of specimens of hypertrophy in connection with their clinical history clearly points in some to the mechanical irritation which protruding masses of more or less prostatic tissue excite in the interior of the bladder. In connection with the treatment of such cases, where the lives of the individuals are not only absolutely useless, but most miserable, I am glad to see there are signs that something now may be systematically done for their relief. Heretofore we have been drawing for any experience we may possess in reference to this point upon what I would speak of as the casualties of lithotomy. There is much, however, in favor of direct surgical interference in these exceptional cases of grave prostatic obstruction and irritation, as the nature of the growth, unlike cancer, renders a return of it improbable. I have now on three occasions deliberately removed, by perineal section, considerable portions of the hypertrophied prostate, with permanent relief to the patients; and I have no hesitation in recommending the adoption of this course in suitable cases, after, if possible, perineal exploration of the part with the finger. Now, three instances may seem very insufficient data for basing such a recommendation upon; but it must be remembered that this is an exceptional remedy for the purpose of meeting exceptional circumstances. No operation of this, or any other kind, would, in my judgment, be warrantable so long as a man can keep himself reasonably comfortable with the use of the catheter, and, therefore, the percentage of cases where more radical measures would seem to me to be indicated is really extremely small. But we must be provided for these, and, though they are oftener met with in the aged and feeble, with reduced powers of repair, whose chances of recovery from any operation are reduced, such means as I am referring to must not be too hastily set aside in these days when the practice of operative surgery, especially in relation to the interior of the body, has been shorn of many of its dangers, and is altogether very different from what it was even at the commencement of the present century. I am induced to make these observations partly because I think it would be a misfortune if operative procedures were extended to what I would speak of as ordinary forms of prostatic obstruction, and partly because I think the risks attending the removal of protruding portions of the prostate have been somewhat exaggerated, and thus surgeons have been debarred from undertaking operations which, in proper cases, have afforded both immediate and permanent relief. So far, I have been able to do all I desired in the way of removing more or less of the obstructing prostate by proceeding from the perineum, which I have always opened with considerable freedom. In connection with the subject of prostatectomy, or removal of portions of the prostate, under such circumstances as I have indicated, I would take this opportunity of expressing the interest with which I read the paper by Mr. McGill, and the no less instructive discussion which followed it, at a recent meeting of the Clinical Society. In this paper the author demonstrates, by instances, how portions of the prostate might be removed by scissors through a suprapubic incision. I am disposed to think that this, on still further trial, will be found the best way to deal with such cases, for it places the operator in view of those projecting masses of degenerated prostate tissue which invariably protrude toward the cavity of the bladder, and which really are the cause of the distressing symptoms of irritation which accompany them. Care, however, will be necessary, as I have just urged, in the selection of cases for operations of this kind, it being distinctly understood that they are undertaken, not because the prostate is large, but because it has induced symptoms which cannot be alleviated in any other way. You may remove the prostate entirely, but this necessarily renders the individual incontinent for life. Lobulated masses proceeding from an hypertrophied prostate, and isolated fibromas in the part, may thus be dealt with to permanent advantage; but this is a very different thing from extirpating the prostate in its entirety, or seriously mutilating the muscular ring, which, under all circumstances, is essential to the integrity of the bladder as a urine-holder.

---

[1] British Medical Journal, June 9, 1883.

The following instance, which I will briefly relate, substantiates the proposition with which I opened this lecture, and as it similarly bears upon the operative point now under consideration, I may consistently close my remarks with it.

In August, 1882, a patient, aged sixty-four, came under my care with symptoms of primary carcinoma of the prostate, which caused bleeding, continuous pain, and irritability of the bladder. As no treatment afforded relief, I performed a free median cystotomy, and proceeded with my finger and a blunt gouge to enucleate the prostate and the growth connected with it. In this I succeeded, with the exception of a small portion in front which I could not get away. There was very little bleeding, and the patient made a good recovery, though he lost the power of retaining his urine. Some degree of retentive power eventually returned, but it became necessary to provide him with an apparatus for controlling the incontinent escape of urine from the bladder. He lived for fourteen months after the operation, and was able to return to his work as a stevedore. He died from a recurrence of the disease in the glands of the groin. I showed a specimen of what was removed, at a meeting of the Royal Medical and Chirurgical Society, in connection with a discussion bearing upon the subject.

CASE OF OBSTRUCTION OF THE BOWELS DUE TO ADHERENT DIVERTICULUM—ABDOMINAL SECTION—DEATH ON THE THIRD DAY FROM HEART FAILURE.[1]

By A. VANDER VEER, A.M., M.D.,

PROFESSOR OF SURGERY AND CLINICAL SURGERY, ALBANY MEDICAL COLLEGE.

Mr. S. V. V——, aged twenty-two; single; native of the United States; by occupation a spinner.

Family history: Nothing was learned, save that several members of the family had suffered from diseases of the heart.

Previous history: Patient had always been well and strong, never having suffered from any disease, but having sustained a fracture of the thigh four years ago.

Symptoms: On Friday evening, November 25, 1887, while at a band-meeting, being a player upon the clarinet, he was taken suddenly with severe abdominal pains, described as being like "green-apple colic" by the patient. He suffered considerably from tenesmus at this time, but had no bloody discharge from the rectum. Patient went immediately to his home, took some cathartic pills, applied hot cloths to the abdomen, and went to bed. Twenty-four hours later, no improvement having taken place, Dr. E. T. Rulison, of Amsterdam, N. Y., was called, who prescribed a cathartic and gave an anodyne.

On the following morning, Sunday, November 27th, patient had vomited during the night; no movement of the bowels; an enema was given, and a small movement came away. Patient's condition did not materially change, and on Tuesday morning I saw the case in consultation with Dr. Rulison. Large liquid and gaseous enemas, and careful watching for serious symptoms, were advised.

Patient had not suffered up to this time any severe and continuous pain. What pain he had was intermittent. There was no disturbance of the pulse or temperature.

On Thursday morning patient had the first attack of stercoraceous vomiting, immediately after which he was brought to the Albany Hospital by Dr. Rulison. When admitted to the hospital his condition was about as follows: Pulse, 88, small and soft; temperature, $99\frac{2}{10}$° F.; tongue heavily coated. Patient continually brought up gas of a feculent odor, and complained of pain in the left iliac region, with little tenderness on pressure; abdomen slightly distended with gas, but soft; slight dulness in lower part of abdomen.

During the day a large enema, five pints of emulsion of olive-oil, was given, and it returned without movement or gas. Later, lower bowels were distended with gas until very painful, carbon dioxide being used. In the evening a rectal tube was passed, apparently eighteen inches, and the injected gas withdrawn. Evening temperature, 100° F.; pulse, 96. Was given morphia, one-fourth grain, at 8 P.M. During the night patient vomited stercoraceous matter again.

Friday morning, temperature, $100\frac{2}{10}$° F.; pulse, 94. As patient was growing worse an exploration was determined upon.

Accordingly, the patient was removed to a room previously prepared, and the abdomen opened, the writer being assisted by Drs. Townsend, Boyd, Hialey, Morrow, Hoadley, and McDonald. As the parietal peritoneum was incised, a fold of intestine presented in the wound, which was dark, very much congested, and distended with gas. The wound was enlarged to admit the hand, when the constriction was found to be in the right iliac region instead of the left. The wound was still further enlarged, the whole length being eight inches. The locality of the constriction was found and brought into view. The following peculiar condition was found: About three feet from the ileo-cæcal juncture a diverticulum of the ilium was found. It was about three inches long, shaped very much like a Bartlett pear. The free end of this diverticulum was attached by adhesions to the cæcum, thus forming a triangular space into which a fold of the ilium had been caught, causing an obstruction and partial strangulation of the bowel. The strangulated bowel was also adherent to the crest of the sacrum. The free end, or base, of the diverticulum was loosened up from the cæcum, a ligature thrown around the pedicle near the ilium, and then removed. The pedicle was next invaginated in the wall of the ilium and peritoneal surfaces stitched over it, by continuous catgut sutures. The intestine was then loosened from its adhesions to the crest of the sacrum, thereby relieving all constriction. The intestine, showing no real gangrenous condition, was cleansed and returned to the abdomen, the wound closed by twelve deep and eight superficial sutures, and dressed with an iodoform strip and Gamgee pads. Patient put to bed with hot water to the extremities.

Time of operation, one hour and twenty-five minutes. Patient reacted very slowly, but he became fully conscious during the afternoon. Becoming quite restless, one-fourth of a grain of morphia was given, and repeated as necessary to procure rest and sleep. Heart's action very weak; was given digitalis and brandy at regular intervals; nutritive enemas were given every four or six hours; evening temperature, $99\frac{5}{10}$°; pulse, 110. On Saturday morning patient was very bright; temperature, 100° F.; pulse, 86. Had slept six hours. Saturday evening, temperature rose to 102° F.; pulse, 120, and thready. Heart's action again became very feeble, and hypodermics of digitalis and brandy were given at regular intervals. Patient gradually sank, and died on Sunday, December 4th, at 11 P.M.

Patient did not vomit after the operation until shortly before death. Bowels never moved, although a little gas was passed during the last day of illness.

---

[1] For the history of, and notes on, this case, I am indebted to Dr. W. E. McDonald, of the Albany Hospital.

Autopsy.—Held eight hours after death. Abdomen only examined. The stitches were first removed, and wound gradually pressed apart. Very perfect union was found to have taken place; no pus. When the viscera were exposed, it was seen that the inflammatory condition presented at the operation had partially subsided; the bowels were less congested, and evenly distended with gas. No effusion into the abdominal cavity. The ilium was ligated at the ileo-cæcal juncture, and about five feet of small intestine removed. Where the diverticulum had been removed, perfect union had taken place, the edges of the wound being smooth and free from undue congestion. One inch on the small intestinal side of and from the diverticulum a circumscribed necrotic condition had taken place, leaving an ulcer, the size of a dime, which extended down through the peritoneal and muscular coats of the intestine. While lifting the intestines from the abdomen this ulcer perforated. Another patch was also found on the small intestine, where the peritoneal coat had broken for about an inch, but which had not perforated.

No further examination was made. This patient did not at any time after the operation present a good, strong pulse. Aside from this there was everything in his condition to lead to recovery. He was hopeful and cheerful to the last; he had been ready and anxious to have the operation performed.

A VERY VALUABLE LESSON FOR THOSE WHO USE ANÆSTHETICS.[1]

By JULIAN J. CHISOLM, M.D.,

BALTIMORE, MD.

R. A——, a robust, healthy child, three years of age, was recently brought to me with a cancerous left eye. The attention of the parents was first called to the yellow appearance of the pupil eighteen months before. The gliomatous mass filled the vitreous cavity, distending the pupil, and obliterating the anterior chamber. The eye was injected and painful. The prompt removal of the eyeball was urged as the only means of protecting the child from a painful death. The operation was accepted by the parents, and the enucleation, under chloroform, accomplished after much difficulty, as the sequel will show.

The child was suffering from a bronchial trouble, but that was not deemed an obstacle to the administration of an anæsthetic. The patient was placed on the operating-table, his clothing loosened about the neck and chest, and chloroform was inhaled from a towel, folded in conical form, with open top. Deep sleep was soon induced.

When the anæsthesia was complete, the operation for the removal of the diseased eye was commenced. The conjunctiva was divided around the cornea, and the tendon of the external rectus muscle was being sought for, when respiration suddenly ceased. The face assumed a death-like pallor, the pulse disappearing at the same time from the wrist. Immediately the child was suspended by the feet, with body and head hanging down at an inclination of seventy degrees, while an assistant volunteered chest-compression for artificial respiration. After a few minutes, signs of a feeble respiratory movement were noticed, a slight throbbing of the neck-vessels was detected, and in time the child evinced its return to consciousness by crying.

He was laid on the table, but would not permit the eye to be touched without a twist of the head, evincing great irritability or sensitiveness of the conjunctiva. As the operation had to be completed, I ordered chloroform to be again administered. Chloroform narcosis was very soon re-established, but before I had time to resume the operation the child again stopped breathing and the pulse disappeared. The body, apparently of a dead child, was once more hung up by the feet, so as to allow blood to gravitate toward the anæmic head and brain, but with no further attempts at artificial respiration. Myself and four assistants watched anxiously the pale face, to catch the first evidence of returning vitality. After some minutes I noticed that the large vessels at the root of the neck showed some fulness, then a slight thrill, and after this the first attempt at a thoracic movement appeared. In ten minutes breathing was sufficiently strong to allow the child to cry again, much to the relief of all of us.

Still, the operation which was so imperatively called for, for the future safety of the child—even the saving of its life from the ravages of cancer—was uncompleted. While the father and mother, both present in the operating-room, were pleading for their child, they were made aware, by the restlessness of the patient when the eye was touched, that nothing could be done without the child going again to sleep, so I once more ordered the inhalation of chloroform. For the third time chloroform narcosis was promptly established, and was followed very soon afterward by suspended respiration and the disappearance of the pulse. Death now seemed to be complete. Immediately the child was hung up by the feet. The absolute quiet of the operating-room was broken only by the lamentations of the parents. All eyes watched the face of the child. Five minutes seemed an hour, and the ashy lips showed, so far, no response. Soon after this a faint effort at respiration was observed, which became stronger with each return of the thoracic movements, and the pulse was again felt feebly at the wrist. When respiration seemed established, complete insensibility continuing, I had the child laid upon the operating-table. As soon as the body assumed the horizontal position, the pulse, not yet strong, disappeared from the wrist, and the respiration ceased, necessitating at once a renewal of the suspension. This curious phenomenon of breathing when suspended, and becoming inanimate when the prone position was too early assumed, was repeated two or three times, respectively. For safety—for I was afraid to lay the child down—I was forced to enucleate the eye while the child was suspended with head downward, an awkward position for operating. It was some time, fully a quarter of an hour, after the operation was completed and the eye bandaged, before I could trust the child in the recumbent posture.

One of my assistants was very anxious to have whiskey injected, and had filled his hypodermic syringe for that purpose; but I declined its use, trusting to inversion alone for resuscitation. The final successful issue of this case confirmed my faith in this invaluable method, which I had used successfully on former occasions, and hence confided in it for the protection of the patient through the trying ordeal. In all, the child must have been suspended in the inverted position for fully three-quarters of an hour. After the last suspension no further trouble ensued. The next day the child was so thoroughly himself that he left the hospital with his parents. He was brought back to the dispensary for inspection, two days afterward, a picture of health.

This case cannot be too carefully studied by surgeons who must continue to use general anæsthetics. It is one of a series occurring to me now and then—I am glad to say, at long intervals—as the consequence of chloroform inhalation.

I am a strong advocate of chloroform, believing it to be the most available remedy of its class. I recognize it as a powerful agent for evil, but at the same time I believe it to be the best of the general anæsthetics. In army life and in civil practice I have had a personal experience of at least ten thousand administrations, and without a death. For thirty years I have had charge of a surgical hospital service, and my daily use of chloroform has been the subject of public professional observation. Sulphuric ether I have seldom used—not one hundred times in my life, and in most of these instances only to exhibit on patients the effects of the various anæsthetics in medical classes at the University of Maryland Hospital Clinic. In the last ten years I have not used it once. For painful operations of very short duration I use the bromide of ethyl, and for all others I use chloroform exclusively.

---

[1] Paper read before the Baltimore Academy of Medicine.

At the Presbyterian Eye and Ear Charity Hospital of Baltimore City, in which institution I am the surgeon-in-chief, I have used chloroform as often as nine times in one day. The consumption of chloroform in this hospital is computed at hundreds of pounds. A pound of sulphuric ether has never been purchased among the hospital drugs, and it is not administered in the hospital.

My rule of practice has always been to do surgical work with the least possible pain, and to refuse anæsthetics to no surgical patient. In the administration of chloroform certain rules are followed. All clothing must be loose around the neck and chest. With adults, an ounce of whiskey is given in advance. In the case of persons under thirty years of age this cardiac stimulant is omitted, unless the patient be feeble. In this hospital practice no precautions as to eating can be observed. The clinic is held at two o'clock every day. Patients are frequently sent from the dispensary to the operating-room one hour after they have eaten a hearty meal. If the patient has been admitted into the hospital wards the day before operation, his dinner is withheld.

Chloroform is administered with the patient lying on his back, and as soon as narcosis is induced the pillow is taken from under his head, so that he lies in an absolutely horizontal position. Should snoring occur, indicating some difficulty in pharyngeal breathing, the chin is drawn forcibly upward. This elevation pulls the anterior wall of the pharynx, with the hyoid bone and root of tongue, forward, making for the air a clear and straight passage from the nose into the lungs. By this movement of the chin respiration becomes immediately quiet and easy. The pulling up of the chin is a much more efficient and convenient means of pulling the root of the tongue forward than by pulling out the tongue with a forceps, as is recommended by some surgeons. It is not always easy at this stage of anæsthesia to get into the mouth, as the lower jaw-muscles may not be relaxed. A proper tongue-forceps is not often at hand, and to tear the tongue-substance with sharp-toothed and yet slipping instruments, with the soreness and swelling which subsequently follow, is an abominable practice that should be abolished. The patient's chin and your own hands are always present, and it only needs knowledge of the method to apply it, and to secure prompt and speedy relief.

The instrument used for the inhalation is a towel folded in cone-form, with the apex of the cone open, so as to permit air to mingle freely with the chloroform-vapor. During the administration the face is closely watched by the surgeon. If the ears remain pink, the heart and lungs must work properly; therefore, there is no need for feeling the pulse. Any failure on the part of either of these organs can be seen in the change of the complexion more quickly than it can be felt at the wrist. When the conjunctiva is no longer sensitive, the patient is considered thoroughly anæsthetized, and the administration of chloroform is stopped. In eye-work the chloroform-administrator must now get out of the way for the surgeon, and therefore the administration of the anæsthetic cannot be injuriously continued. Herein lies one great point of safety with the ophthalmic surgeon.

As I have previously stated, I deny chloroform to no surgical patient. Prior to the discovery of cocaine as a local anæsthetic, I administered chloroform for cataract-extractions, enucleations, iridectomies, squints, lid-operations, passing of lachrymal probes, or, in fact, any painful operation whatever, and even for the examination of irritable eyes in children. These patients were of all ages, from infants to octogenarians, and of course represented every condition of disease and health. If restoration to sight could be obtained, operations were performed on the blind regardless of the diseased conditions of other organs. Some patients were strong, and some were very feeble, with lung, heart, and kidney diseases. No pathological lesion in any other part of the body deters me from the use of chloroform should an eye-operation be required.

Cataract patients are usually old; most frequently they exhibit decided senile changes. I suppose an average of sixty years of age would represent this class of patients; seventy, seventy-five, to even eighty-five, ninety, and ninety-five, are at times the respective ages; ninety-six is the extreme age at which a successful cataract-extraction has been performed under chloroform at the hospital. It is well known that fatty hearts are very frequently found in old subjects in dissecting-rooms. My cataract-operations now reach fifteen hundred. Of these, many must have had fatty hearts. Prior to the last two years, before cocaine came into use as a local anæsthetic, I gave chloroform in all cataract cases, and therefore must have given it to many patients with fatty hearts.

Very feeble heart-pulsation, with irregularity of action, I frequently met with in old patients. With such I always increased the amount of whiskey, which I administer in advance of the chloroform inhalation. I consider it much the safer practice to put whiskey into the stomach, where it is ready for use, if wanted, and where it can do no harm if not needed. I have never had occasion to inject whiskey or ether into the rectum or under the skin. The hypodermic syringe forms no part of my chloroforming apparatus.

So far, after thirty years of active surgical life, I can conscientiously say that in no single case have I had cause to regret that I chose chloroform as the anæsthetic. I always give chloroform in the presence of physicians—never alone—and most frequently with the whole surgical staff of the hospital present. Had death from chloroform occurred in my practice, it would have received, necessarily, prompt publicity. That I have never had one, and that I have never refused chloroform to any patient received into the hospital for surgical treatment, is a fact well known.

I repeat, that in my long experience I have never had a death from any anæsthetic, although I have given chloroform to over ten thousand persons of varied sanitary conditions; but I freely acknowledge that I have come very near having a fatal ending more than once. I have had four cases of sudden arrest of respiration, with failure of the heart's action, when death would have inevitably been the final result had not prompt and proper means been taken to resuscitate the patient.

Experience under these severe trials has made me a firm believer in the efficacy of inverted suspension for the restoration of life in patients apparently killed by chloroform. I feel convinced, from my own experience with this invaluable method, that many of the dead from chloroform might have been resuscitated had the surgeon hung up immediately by the feet the inanimate body, instead of wasting time in applying hypodermic injections, cold-water splashings, spanking, fanning, electricity, or even attempts at artificial respiration, the remedies which text-books on surgery recommend. Do any or all of these things if you will, but hang up the patient first, and that instantly, as soon as the heart and lungs fail. It is the horizontal position that is fatal in chloroform-poisoning, and leads to death if the body is kept in it, as all the reports of fatal cases with chloroform show.

With myself it has become a matter of faith, and in suspension alone I now place my confidence. So far it has served me most successfully. Had I not used suspension in the four cases referred to, most of them, probably all of them, would have died. Then my percentage of fatal cases would have corresponded with the average chloroform mortality: one in twenty-five hundred cases of administration.

By suspended respiration I refer to the complete arrest of all respiratory movements. I do not mean that very feeble state of heart and lung action, accompanied by pallor of face, which frightens so many physicians, and which I know only foreshadows the approaching vomiting. This condition of depression I see with a great many chloroform patients. With me it is only a signal that a basin should be in readiness. I often hear physicians, in giving their experiences, speak of their very narrow escape from a fatal chloroform-administration, meaning this stage of depression, which one familiar with chloroform, from its daily administration, would almost call normal.

Many years ago I became very much impressed by certain experiments made by Dr. Nélaton—that well-known French surgeon—to show that in chloroform narcosis the respiratory and cardiac centres were weakened by an anæmic condition of the nervous apparatus, the exposed brains of animals bleaching as chloroform-vapor was inhaled by them to complete anæsthesia. When this whitened appearance indicated such a condition as to give but little of the needful blood-stimulus to the great nerve-centres, their functions ceased in a regular order: First in volition, next in voluntary movement, then in general sensation, and finally in the arrest of involuntary or organic movements, including the action of the heart and lungs, and then death promptly ensued. In his experiments he found that when a number of rats had been thoroughly narcotized with chloroform, those which he would immediately hang up by the tail would slowly revive, while those left supine on the table died. If, when animation commenced to show itself in the hung-up animal, the rat was laid down too soon, breathing would again cease, and the rat would die, unless immediately suspended, when the respiratory and cardiac actions would be resumed. It was only after a sufficiently long suspension, giving the brain and heart ample time to have supplied to them, by gravity, a desired amount of blood, that death could be prevented. If the animal was not already dead, suspension alone would restore animation. The knowledge of this fact is daily put into use by vivisectionists in their experiments upon animals under chloroform. The case of the child which I have reported is really in the line of these experiments, and clearly shows the danger of the horizontal position when the heart and lungs fail. The suspending of the human body by the feet to restore animation in chloroform-poisoning was Nélaton's great discovery, and is known as his method of restoring patients to life when, under chloroform-anæsthesia, respiration has suddenly ceased. The knowledge of, and faith in, this method has served me well on many trying occasions. To it alone I attribute my clean record of over ten thousand cases of general anæsthesia and no death.

Eighteen months since I ordered chloroform to be administered to a patient, eighty years of age, who had his right ear a mass of epithelioma. The pinna was much enlarged, and an offensive, painful ulcer, with ragged outlines, covered nearly the whole surface. The object of the operation was to remove all of this fetid, discharging surface, and to close as much of the wound as possible, by quick union. His history, as given by himself, was quite a curious one of coincidences. He had been married twice. His first wife had a cancer of the breast for which an operation had been recommended by his family physician. She died under chloroform before any incisions were made. His second wife was brought to me six years ago, suffering from a malignant disease of the socket, involving the eyeball, the eyelids, and skin of cheek. The cervical glands at angle of jaw were secondarily infected. I declined to operate, and advised against it, as no good could possibly come from it. She returned, disappointed, to her distant home. Against my advice, the local physicians urged the operation, and in her anxiety to get rid of the cancer, she yielded to their solicitations. They undertook it, and she died during the operation—they said, from the effects of chloroform. There was no blood-relationship between himself and either of his two wives, and yet he also had a cancer for which an operation under chloroform was advised. He was of a robust frame, although eighty years of age. In his desire to get rid of the fetid discharge, he submitted without hesitation to the course recommended.

First a full dose of whiskey was taken, and then chloroform was administered by the resident physician of the hospital, aided by the medical staff. I had left the operating-room for a few minutes, to show to a medical visitor some cases of interest in the wards, when the nurse ran to inform me that the man whom I had just left was dead. I hastened with my medical friend to the operating-room. I found one of the physicians trying thoracic compression for artificial respiration on an apparently lifeless body, lying flat upon the operating-table. I had this immediately stopped, and under instructions the four doctors present, with the nurse and the brother of the patient, held up the lower end of the operating-table so as to incline the body and head at an angle of over forty-five degrees, using at the same time all of their restraining force to keep the body from sliding off the table. Nothing else was done. With the inanimate body in this way suspended, we quietly and anxiously awaited results. In a very few minutes we had the satisfaction of seeing slight thoracic movements, then the ashy, livid face lost its death-like hue. When respiration became fully re-established, the table was lowered, and the operation safely completed, no more chloroform being required in this case.

A third case occurred in my hospital experience eight years ago. It was that of a woman, forty five years of age, who had suffered frightfully from repeated attacks of irido-cyclitis. I had urged an iridectomy as a means of protection from suffering, but on account of timidity she had steadily refused to submit to it. After many sleepless nights of agony, and being worn out by the pain, she finally consented to be operated upon. Loss of sleep and the constant pain had enfeebled her very much. She was given two ounces of whiskey before being put on the operating-table. Complete anæsthesia under chloroform was soon induced. The eye-speculum was being placed in position, when respiration suddenly ceased. No one was feeling the pulse, as I was standing over the face, watching the skin-circulation. She looked dead, and we thought her so. Fortunately, there were several physicians present, and immediately she was hung up by the feet. While I watched the effects of suspension on the face, some attempts were made, by rhythmical abdominal pressure, to force air from the lungs and thereby excite a respiratory movement. This, however, was soon desisted from, being inconvenient, and, as I thought, useless. After a few minutes of suspension, respiration was gradually re-established.

The patient, brought back to life, was again laid upon the operating-table. She was perfectly relaxed, and I hoped that I could do the iridectomy without any further anæsthesia. The moment I touched the eye a flirt of the head exhibited a degree of irritability, showing very plainly that it was impossible to attempt it. As the pulse by this time seemed perfectly re-established, and the stomach contained a good quantity of whiskey (there had been no vomiting), I determined again to give her chloroform. A very few whiffs from the charged towel brought on full anæsthesia, and with every promise that the various steps of the operation could now be successfully carried out. The speculum was applied, the eyeball seized, and the cataract-knife had transfixed the cornea, when respiration and cardiac action again stopped. The patient now seemed quite dead. The eye-instruments were quickly removed, and the patient in an instant was hung up by the feet, with head down. No attempts were made at artificial respiration, nor were any other means used for resuscitation but the inversion, not even throwing open the windows for fresh air. As still as death, we watched the suspended body. After a few minutes, which seemed a very long time to us, a feeble respiratory movement was detected. This slowly developed into full breathing, and brought back the pulse, and with it life to our patient.

She was again laid on the table, utterly limp, but breathing freely. When the eye was touched the head made, again, a sudden movement, showing a degree of conjunctival irritability which rendered the completion of the eye-operation impossible. The question now before me was, whether I should leave the eye with an operation half performed, or protect the patient from future suffering by completing what I had started out to do. After consultation I concluded to perfect the operation, and, with an abiding faith in the efficacy of suspension, I ordered chloroform again to be administered. For the third time quiet sleep was quickly induced, and, fortunately, with no further complications or trouble, the operation was successfully and safely completed.

Twelve years ago, a fourth case occurred under my treatment. A gentleman brought to me his two boys, one eight, the other six, years of age, both subjects for squint-operation. Such operations I frequently perform in my office, with the aid of one professional assistant. The elder boy was put to sleep under chloroform, the tenotomy of the rectus completed without trouble,and he was laid upon a lounge, vacating my reclining operating-chair for the younger boy. He also bore chloroform apparently as well as his elder brother, and under its narcotic influence the squint-operation was speedily completed. After I had removed the eye-speculum, and cleansed the conjunctival sac of blood, respiration suddenly stopped, the pulse disappearing from the wrist, and accompanied by the death-like appearances which belong to this startling condition. Fortunately, I was sitting at the head of the patient, and I immediately tilted down my end of the operating-chair, getting my assistant to elevate the foot-end, so as to secure an inclination of forty-five degrees, with the head of patient downward. After a few minutes blood gravitated into the head. By stimulating the nerve-centres, it started into action those organs so essential to life. Breathing was finally re-established, and with it the circulation.

These four cases of sudden arrest of the respiratory functions, with failure of heart's action during chloroform-narcosis, occurring in my own individual practice, I feel assured that most of these patients would have died had they been left in the recumbent posture, regardless of what may have been done otherwise for their restoration. Fanning, fresh air, water-splashing, spanking, whiskey or ether injections, electricity, artificial respiration—all of them the remedies which physicians rely upon—go for very little, provided the patient be left supine. General experience, unfortunately, has too often shown this. In my experience with chloroform, in cases of suspended animation, all of these means for resuscitation are useless, provided the patient be hung up by the feet without any loss of time, so that blood may flow to the anæmic head and heart, and stimulate the nerve-centres before the vital spark goes altogether out. A fire cannot be rekindled by adding fuel if there be no live coals in the grate. Fortunately, suspension of the body needs no preparation nor apparatus for its immediate application. It only needs vigilance on the part of the operator. Should fright make him forget his duty, then precious minutes are lost in trying useless remedies, and these precious minutes can never be recalled.

That all of my cases of apparent death from chloroform should have recovered is not merely good luck, nor is it accidental. I know that chloroform, ether, and ethyl are powerful agents for good, and also for evil. I am sure that I can kill any patient by the abusive or careless administration of either of these invaluable remedial agents, just as I am sure that I can be burned by any kind of heating apparatus, which I am so dependent upon for genial warmth in winter.

The successful administration of an anæsthetic does not consist merely in holding before the nose of the patient a cloth with the narcotizing agent poured upon it. Skill, care, prudence, judgment, and courage in time of need are all necessary to guard the narcotized patient from danger. Too little of the anæsthetic—not enough to protect the important vital centres from the influence of painful reflex actions—is as dangerous as an overdose of the narcotic inhalant. Many of the fatal accidents occur in the hands of timid physicians or dentists who are afraid to administer enough of the anæsthetic to secure the stage of safety, the immunity from reflex disturbances, and who lose their heads in fright when the danger which their want of confidence has induced presents itself.

The lesson which I would impress upon everyone who uses chloroform, sulphuric ether, or the bromide of ethyl for general anæsthetic purposes is, that prompt suspension, with head down, is the remedy for suspended animation suddenly coming on during acquired narcosis.

No surgeon recognizing the responsibility of his work should ever give an anæsthetic without having someone present. Should there be any sudden and alarming weakening of the heart's action and of respiration—for they always go together—without a minute's delay hang up the patient. Should the patient be bulky, and should there not be force enough present to elevate the foot of the table or bed, be the patient man or woman, while you stoop, throw their legs over your shoulders, hang on to their feet in front of you, and then lift yourself. The patient's body, as you get upon your own feet, will hang from your back, with the head down. Now you have time to call for more help if you need it. Never wait for the help to come before you practise suspension, because with the moment's delay your patient may have passed from dying into death from which there will be no more earthly awakening. When too long delayed—and one minute is a fatal loss of time—suspension is as useless as the other recommended remedies, and can then do no good.

Should the case have been one of needless fright, with only weakening, and not suspension, of the vital functions, no harm has been done. The feeble pulse will always respond promptly to the suspension. It is my constant practice to use suspension for restoring strength to the heart's action after the administration of chloroform, where there is cardiac depression and weak breathing. I use this means of restoring vigor where others use the more objectionable and less efficient hypodermics of whiskey or ether, or the inhalations of nitrite of amyl. It is very instructive to observe how promptly the pallor leaves the face, and how strong the pulse will become, as blood gravitates toward the head. Should vomiting occur when the head is hanging down, this suspended position is better for the patient than when lying upon the table, because there is no fear of food-particles getting into the larynx. Inversion of the body gives the contents of the stomach free vent.

Such confidence do I feel in the value of suspension with chloroformed subjects that I am sometimes disposed to believe that the vital centres cannot fail with the head hanging down.

Not long ago, in the presence of the medical class of the University of Maryland, I removed by ligature a very large staphyloma from a child one year old. It was the result of purulent ophthalmia of the newly born. The prominence of the opaque cornea was so great that the lids could hardly close over it. The summit of the tumor was being irritated by the constant friction of the lids in winking, and its removal became necessary for the comfort of the child. Under chloroform-anæsthesia I transfixed the eyeball at the base of the tumor by two long, curved needles, placed at right angles to each other. Behind these, acting as a shoulder, I applied the ligature for the strangulation of the tumor. The medical class could not see from the benches the various steps of the operation upon so small a portion of the body, and from the large number of students present only a few could have crowded around the operating-table. After the ligature had been secured, and before the needles were withdrawn, I did not hesitate to hang up the infant by the heels, with head suspended vertically downward, and then walked with it in front of the benches, so that the students could inspect the eye. To the uninitiated this would appear a heartless and dangerous proceeding. My experience and consequent faith in suspension had taught me that this inversion was the safest position for the narcotized child during the tedious inspection.

Clinical Department.

DEATH FROM INTESTINAL HEMORRHAGE DUE TO VASCULAR TUMOR.[1]

By F. W. MERCER, M.D.,

CHICAGO, ILL.

The history of this case was communicated to me in part by Dr. Converse, the attending physician: Annie W——, single, aged thirty-four, was always considered in good health. She had menstruated regularly, without undue pain or other trouble until within the past year, when it was observed that the flow was not quite as copious as before. All the other bodily functions had been regularly performed, so far as her friends knew. She was of cheerful disposition, vivacious, and physically strong, being able to toss her sister's child (weighing about twenty pounds) up at arm's length above her head.

About a year ago she consulted a leading practitioner of this city, to whom she complained of a throbbing sensation in the left inguinal region, and also some slight digestive disorder. The doctor informed her that he considered the throbbing due to the presence of gas in the intestine, and prescribed some digestive.

After this the patient was in her usual health, not making any special complaint till the morning of October 16, 1887, when she said she felt tired and reclined upon the bed in her room. About 11 A.M. she had a movement of the bowels, consisting almost entirely of blood, but not large in amount. Dr. Converse, who examined the stool, concluded it was due to "bleeding piles." Absolute rest was ordered. At 12.30 P.M. the patient arose and entered the bath-room, where she fainted while passing another bloody stool. She was carried back to bed, and soon revived. Dr. Converse saw her again, and ordered pyrogallic acid and ergot with brandy at short intervals.

From this time till 9 P.M. there was increasing restlessness and involuntary discharges of blood at short intervals, but, as the blood was received upon cloths, any accurate estimate of its quantity was impossible. At about this time I was called to see the patient in consultation. I found her tossing from side to side of the bed, groaning, and complaining of pain over the umbilicus. Her features were shrunken and pinched, the surface blanched and clammy; the face was very cold to the touch, and the pulse was barely perceptible. In fact, the patient appeared moribund from hemorrhage. An examination of the abdomen was made, and the presence of a symmetrical tumor, of globular form, was discovered in the median line, just above the pubis. An enlarged uterus was suspected as the possible source of the hemorrhage; an examination *per vaginam* disclosed a very minute os uteri, an elongated cervix, but no indication of hemorrhage.

Hot-water bags and bottles were applied to the surface, warm blankets were packed about the body, and brandy was given subcutaneously, with aromatic spirits of ammonia by the mouth. Transfusion was thought of, but, the means not being at hand, it was not tried. Dr. E. W. Sawyer was called; but little could be done, the patient being *in articulo mortis*, death taking place a little before 10 P.M.

Section, fourteen hours after death: Dr. E. D. Converse, Dr. E. W. Sawyer, Dr. William Barry, Dr. Frank T. Andrews, and myself being present. The section was made by Dr. Frank T. Andrews. The body appeared well nourished; the rigor mortis well marked. Upon reflecting the abdominal parietes, the intestines appeared rather pale, and not unduly distended. At the lower part of the hypogastric region a tumor was found resting in the median line; it was nearly spheroidal in form, about 9 ctm. in diameter, and weighed 455 grammes; moderately firm, and attached by a slender, short pedicle to the small intestine (ileum) about fifteen inches above the cæcum. Upon section of the ileum, an oval opening was discovered upon its mucous surface, about 4 mm. by 3 mm.; this opening corresponded to the attachment of the pedicle upon the peritoneal surface, and communicated directly with an artery of about 4 mm. calibre. It was undoubtedly from this opening that the fatal hemorrhage had occurred. There were extensive old adhesions of the intestines and peritoneum. Both the right and left kidney showed a greatly reduced cortex, and the tubuli and pelves were filled with pus. The liver was very fatty and friable, breaking under pressure like old, granular tallow. The body of the uterus was converted into an irregular, lobulated mass, the whole measuring about 8 ctm. by 4 ctm. The nodules were firm and dense. The thorax was not opened. Microscopic examination of the tumors involving the uterine body showed them to be myomata having the usual character of a uterine fibroid. The intestinal tumor also proved to be a vascular myoma, the muscular tissue showing in many places the result of inflammatory action within the tumor itself.

The whole case may, I think, be considered unique; but the most extraordinary feature is, that a person suffering from such a complication of diseases, any one of which was most grave in character, should be about doing clerical work, without complaint, and should also bear the appearance of fair health.

2600 Calumet Avenue.

THE USE OF CALOMEL IN THE PREVENTION OF PITTING IN SMALL-POX.

By JOSEPH DRZEWIECKI, M.D.,

ASSISTANT PHYSICIAN IN THE UNIVERSITY CLINIC OF THE HOLY GHOST HOSPITAL, WARSAW, RUSSIA.

In order to prevent the forming of pustules, or the disfiguring marks, on the face in small-pox many methods have been recommended, but none can boast of sure and successful results.

Among the remedies which have gained great reputation may be mentioned the application of indifferent fats, collodium, tincture of iodine, a solution of carbolic acid or of corrosive sublimate, also cutting of the pustules and cauterizing them by nitrate of silver, and, finally, various forms of masks on the face, or continual cold compresses. Although the latter would seem to give the best results, it cannot be always employed, either because not everybody can support cold compresses, or because this application is troublesome to make, as it requires constant attention.

Having frequently had such cases under my care, during the small-pox epidemic of last summer at Warsaw, I convinced myself that calomel, applied as powder on the face, does not prevent the development of vesicles from the papules; but when vesicles or pustules were developed it caused them almost immediately to dry up, and in this manner prevented the formation of marks. How and why calomel acts in these cases I do not pretend to explain. However, we may suppose that pos-

---

cological Society on December 16, 1887.

sibly several agents have a share in producing this result. Perhaps the calomel acts partly as calomel, partly as sublimate, or partly, perhaps, as metallic mercury, since calomel becomes decomposed into these two latter substances under the action of light; and the mercurials then act either by immediately destroying the micro-organisms or by preventing their development.

In my cases I employed calomel alone, in the form of powder, dusting it over the face, or I mixed it with starch in the proportion of twenty to thirty per cent. I suppose that, instead of calomel, the oxide of mercury might also be employed with success. As regards the strewing of calomel into the eyes, sometimes adopted with a therapeutic aim, we need not fear that it will do them any injury.

SOME OF THE USES OF ANTIPYRIN.

Dr. Wm. H. German, of Morgan Park, Ill., writes: "From March 8 to 21, 1887, I had under my care a young man suffering from the effect of a prolonged debauch. The usual sedatives had apparently lost their effect upon him, and he demanded morphia, having previously used it on similar occasions. Being unwilling to administer that drug, I gave a five-grain dose of antipyrin as a placebo. Under its influence the patient slept two or three hours, and an increase to fifteen grains produced eight hours of quiet, restful sleep.

"Since that time I have employed antipyrin in many cases of insomnia with uniformly satisfactory results, except in two cases of long standing, in which it appeared to be nearly inert.

"In trifacial neuralgia, in hemicrania, in migraine, in congestive dysmenorrhœa, in lumbago, it affords prompt relief, and in many cases is curative. In my experience it is useless in hepatic colic. A fifteen-grain dose will quiet an aching tooth for twenty-four hours. In two cases it has seemed to terminate typhoid fever, when given in full dose at the end of the second week. It diminishes and, in some cases, prevents the hectic of phthisis.

"Some recent writers in The Medical Record have mentioned the insolubility of antipyrin. There must be a mistake. It is as readily soluble as morphia. Two incidental objections lie against this useful drug—its cost, and its name."

The Various Effects of Gall-stones.—In an address on "Some of the Rarer Symptoms produced by Gall-stones," read by Dr. W. M. Ord (*The British Medical Journal*), he says that the various effects of gall-stones may well make us pause and meditate. We have to deal with biliary colic very often; to know it as a process involving intense pain, and many other distresses; to see it make its progress commonly to a satisfactory end. As regards the suffering produced, we are impelled to do all that we know toward relief; as regards the outcome, we may be generally hopeful, if not confident. Biliary colic being the most commonly apparent indication of the presence of gall-stones, we may be ready to see in gall-stones things productive of much suffering, but having in their aspect more of the troublesome than the deadly. Gall-stones, indeed, travel so commonly by the same line, that we tend to believe that, in spite of delay occurring now and then, the terminus must be reached. A permanent block occurring on the line sends the travelling stone into many by-ways of disaster. We may find the stone in such case causing intermitting abscess, causing perforation of the gall-bladder, causing pyrexia, causing glycosuria, causing distant inflammations, probably malignant disease, and certainly serious hemorrage.

He rises from the contemplation with increased respect, born of sad experience, for the gall-stone. If biliary colic be no very terrible illness, the gall-stone is to be dreaded and feared in proportion as there is less of the colic and more of accessory symptoms.

Progress of Medical Science.

The Decomposition of Potassium Iodide in the Body.—The importance of potassium iodide in medicine has led to many attempts to trace its exact action in the body. Binz, along with Kämmerer, Buchheim, and others, maintain that it is decomposed, and iodine set free by the oxidation of the potassium by nascent oxygen or else ozone. Dr. Gaglio reports at some length the results of his experiments made with a view to testing this hypothesis. Binz points out in support of his theory that when leaves have been bruised in water along with carbonic acid and potassium iodide, proof of the free iodine thus obtained is given by the blue staining of starch. Dr. Gaglio, repeating the experiment with lettuce, admits its truth so long as the green parts only of the lettuce are used, and so long as the leaves are fresh. With the inner part of the stalk, or the leaves themselves a day after they have been picked, the experiment fails, so that the oxidation-process assumed can hardly be a property of all cells—vegetable and animal—as Kühne, Haeckel, and Schultze are inclined to think. A mixture of fresh animal tissues of all kinds with carbonic acid and potassium iodide did not show any free iodine, even when the tissue was living, as in the case of some frogs used; nor even when the alkaline surroundings of a muscle were turned acid by its frequent electrical excitation. As an experiment on the oxidation of potassium iodide in the living rabbit, 15 grains of the salt was injected on one side, and 15 grains of turpentine on the other, the turpentine carrying ozone with it. The animal was killed after twelve hours, and no trace of iodine was found, in the shape of brown discoloration of the turpentine, or of the blue color of starch applied to the tissues where the salt had been injected. It has been suggested that the iodine gets free in the catarrhal secretions from mucous membranes which potassium iodide provokes. That, Dr. Gaglio thinks, is probable, for he finds free iodine result from a mixture of saliva or nasal mucus with potassium iodide and starch, if left to itself for a few days; and a similar decomposition might take place in the secretions of the body which are not too quickly disturbed.—*The Practitioner*, November, 1887.

Delivery through the Vagina in Extra-uterine Gestation.—At a late meeting of the London Obstetrical Society (*The Lancet*, December 3, 1887), Dr. Herman read a paper on this subject. The author said that no general rules could be applied alike to all cases of extra-uterine gestation and at all periods of their history. Different cases required different treatment, and individual cases required different treatment at different periods in their history. He would consider in what cases and at what time an extra-uterine gestation cyst might with advantage be emptied through the vagina. The author first related a case under his own care. The patient was forty years of age. The extra-uterine pregnancy was preceded by a long period of sterility. Symptoms like those of rupture of the sac occurred at about two months' pregnancy. Fœtal movements ceased at eight months' pregnancy. At nine months spurious labor-pains occurred, and lasted nearly a month, and these labor-pains were accompanied by spontaneous dilatation of the cervix. Then the pains went off, the breasts diminished in size, and the cervix contracted. To attain certainty as to the diagnosis, the cervix was subsequently dilated, and this dilatation was followed by febrile disturbance. The cyst was then opened per vaginam, the child removed, and the cyst frequently washed out with carbolic solution. The placenta came away on the sixteenth day. Two months and a half afterward the cyst had completely closed. The author had collected thirty-three cases in which an extra-uterine gestation cyst had been emptied by the vagina, and from an examination of them he drew the following conclusions:

1. The operation of opening an extra-uterine gestation sac by the vagina early in pregnancy, before rupture has taken place, by the cautery knife or otherwise, is a dangerous and unscientific proceeding. Abdominal section ought always to be preferred to this. 2. Soon after rupture has taken place, when interference is called for to arrest hemorrhage, abdominal section is more likely to succeed than vaginal. 3. When rupture has taken place, and the effusion of blood is followed by pyrexia, the indications for incision of the vagina are the same as those in hæmatocele from any other cause. 4. At, or soon after full term, before suppuration has taken place, there may be conditions which indicate delivery by the vagina as preferable to abdominal section. These are, 5, when the fœtus is presenting with the head, breech, or feet, so that it can be extracted without altering its position; and, 6, when it is quite certain, from the thinness of the structures separating the presenting part from the vaginal canal, that the placenta is not implanted on this part of the sac, and it is not certain that the placenta is not implanted on the anterior abdominal wall. 7 If the child cannot be delivered by the vagina without being turned, abdominal section should be performed. 8. No attempt should be made to remove the placenta. 9. The after-treatment should consist in frequent washing out of the sac. 10. After suppuration has taken place, the spontaneous opening of the sac into the vagina is one of its more favorable terminations.

Radical Cure of Hernia.—At the Société de Chirurgie M. Ferrier, speaking on the treatment of congenital hernia, said that the first thing which should be taken into consideration was the age of the patient, as congenital hernia of the child differed essentially from the same affection in the adult. In the child the hernia can be cured spontaneously or with the use of a bandage, although there are cases where an operation is necessary. In the adult the question was much more simple, being reduced to one of two conditions—either the testicle is in place or there exists an ectopia. If the former be the case the organ should be respected, but if the contrary be observed, extirpation will be necessary. He performed the operation at least thirty times without one failure. The chief difficulty was found in the dissection of the sac, but, that done, the rest was easy. Union by first intention was always sought for. M. Berger considered that congenital hernia was rarely witnessed in the adult, and further, that hernia observed after the age of fifteen and before twenty may be cured by the use of a bandage night and day. Even if the hernia persisted he found by experience that the danger of strangulation was much less than in the acquired form, and in any case the strangulation yielded much more readily to taxis and chloroform. As to the operation for radical cure, he did not consider it to be so benign as he would be led to believe, and he had arrived at the following conclusions: 1. In congenital hernia no operation should be made before the age of fifteen. 2. After that age an operation might become necessary, but every other means should be at first exhausted. 3. The existence of an ectopia would be a special indication of the operation, provided the patient had passed fifteen. M. Auger presented a man on whom he operated; he allowed the wound to suppurate in order to obtain a strong cicatrix. Several members said that no cicatrix was equal to that produced by first intention. M. Lucas thought that M. Berger was much too sanguine in respect to the treatment by bandages, or that he must have been very fortunate in his cases. M. Ferrier and himself operated more than a hundred times and never lost a case. He was of opinion that each time a patient asked to be relieved of his hernia it should not be refused him, as bandages were a great annoyance.—Paris Correspondence *Medical Press*, December 7, 1887.

The Bacillus of Whooping-cough.—Dr. Afanasieff has succeeded in finding and cultivating what he believes to be the true bacillus of whooping-cough. This microbe differs distinctly from all other bacteria which have been described. It is somewhat like Friedländer's pneumonia-bacillus, but is shorter and thinner than the latter; besides, in gelatine it does not form nail-shaped cultures, those which are produced having no hemispherical head. Its potato cultures, too, are quite different from those obtained from Friedländer's bacillus. Afanasieff's bacillus exhibits a remarkable degree of vitality, for jelly cultures that have become dry and have been kept for four months, appearing under the microscope to be more or less destroyed, are still capable of producing fresh cultures when fresh media are inoculated from the dried mass. Dr. Afanasieff's researches were chiefly made from the sputum of some of his own children, who were affected with whooping-cough. The mouth was well washed out with a permanganate solution, and the mucus coughed up after the next paroxysm or two examined. In this mucus, after staining with methyl-violet, and in the pus-corpuscles contained in it, the bacilli could be seen with a magnifying power of from 700 to 1,000 (Zeiss' eye-piece 3 or 4, $\frac{1}{12}$ oil immersion objective) as short rods, sometimes single, sometimes in twos, or even in short chains running in the direction of the mucus, sometimes again in small clusters. Their length was from 0.6 μ to 2.2 μ. Of course other bacteria were found. Pure cultures, however, were easily made on agar-agar, meat-peptone jelly, potato, etc. Dogs and rabbits were inoculated with a fluid culture mixed with chloride of sodium solution, some by means of injections into the trachea, others by direct injections into the lungs. All the animals were seriously affected, and many of them died. The symptoms were somewhat similar to those of whooping-cough, including cough, dyspnœa, and redness of the eyes. Many of the cases were complicated by broncho pneumonia. On examining the bodies of those animals which died, the mucous membrane of the air-passages was found much reddened, and coated with a tenacious clear mucus, in which, as well as in the pneumonic patches in the lungs, the bacilli were found. Similar appearances and the same bacilli were observed in the bodies of children who had died from whooping-cough. As to treatment, inhalations and spray of various antiseptic drugs would appear to afford the most ground for hope in relieving and shortening this complaint. The author points out that the quinine, benzoin, and other substances which have been used as applications to the nasal mucous membrane by Michael and others, under the idea of combating a reflex affection, are really, perhaps, beneficial from their property of destroying bacilli.—*The Lancet*, December 3, 1887.

Color-blindness a Brain Affection.—Professor Ramsay believes that the particular defect giving rise to color-blindness lies, not in the eye itself, but in the brain. Certain persons, he points out, are incapable of judging which of two musical tones is the higher, even when they are more than an octave apart. Yet, as such persons hear either tone perfectly, the defect is not one of deafness. He accordingly argues that in such persons the brain is at fault, and thence proceeds to the assumption that it may be equally true that the inability to perceive certain colors is not due to a defect in the instrument of sight by the eye, but to the power of interpreting the impressions conveyed to the brain by the optic nerve. If this is the case, the problem is no longer a physical one, it falls among those with which the mental physiologist has to deal.—*The Medical Press.*

The General Treatment here both for Primary and Secondary Syphilis is a centigramme (gr. $\frac{1}{6}$) of corrosive sublimate injected into the buttocks every other day or daily. The solution used is: Sod. chlor., 6; hydr. bichlor., 1; aq. dest., 100.—*Vienna Correspondence Birmingham Medical Review.*

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY
WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, January 21, 1888.

HEMATOGENOUS ALBUMINURIA.

ACCORDING to Immerwahr, whose inaugural thesis appears in abstract in the *Allgemeine Medicinische Central-Zeitung*, there is a hematogenous variety of albuminuria which is characterized by the complete absence of pathological change in the heart or kidneys. It is, perhaps, not always remembered that Bright originally explained the disease which bears his name by assuming some anomaly in the constitution of the blood-serum ; in other words, by the doctrine of hematogenous albuminuria. His later and better-known researches, by drawing attention to the histological lesions found in nephritic kidneys, quite eclipsed his older views.

Semmola, however, has recently attempted to revive the doctrine in question, but there can be no doubt that his generalizations have been too wide, and his positive assertions too dogmatic. At any rate, his opinions are not shared by the great majority of observers.

On the other hand, it has been demonstrated that such conditions as hypalbuminosis (hydremia) and hyperalbuminosis lead to the appearance of albumin in the urine. In profound cachexia and in pernicious swelling Dr. Immerwahr has also discovered a condition of "hematogenous albuminuria." We would remind the author in this connection, however, that the heart and kidneys are, as a rule, more or less profoundly affected in the conditions named, and that, therefore, his own definition of this variety of albuminuria would scarcely be applicable here.

Much has recently been said about physiological albuminuria, a term which to us has always seemed quite objectionable, for the reason that albumen, in appreciable quantities, is not a physiological ingredient of urine. Although not suggested by Immerwahr, it may be well, in future, to speak of "hematogenous" albuminuria in place of the "physiological" condition.

As regards the treatment of albuminuria without renal lesions, it does not, according to the author mentioned, differ essentially from the therapy of true nephritis. A milk-diet is advocated as applicable to most cases, and drugs are to be employed only for particular indications.

THE CURABILITY OF DIABETES.

BOUCHARDAT defines diabetes as a disease in which the urine contains constantly a notable proportion of sugar. Most writers add to this the statement that the condition is accompanied with excessive thirst, excessive or perverted appetite, progressive emaciation, muscular weakness, and languor. Glycosuria is a name once used simply to indicate that saccharine urine was being passed. Of late, however, attempts have been made to make it stand for a more or less distinct disorder in which the amount of sugar is small and the presence of it in the urine not constant. It is not possible as yet to separate diabetes and glycosuria sharply, but, for convenience, the distinction suggested by Bouloumie (*L'Union Médicale*, November 10, 1887) is a serviceable one. According to this writer, in diabetes, with or without azoturia, the sugar does not disappear from the urine when starches and sugars are withheld from the patient. In simple glycosuria, with or without azoturia, the sugar disappears when starches and sugars are withheld. The time which it takes to cause sugar to disappear in glycosuria, so called, by proper diet is from three to seven days.

In determining the effectiveness of drugs in the treatment of diabetes, the test of withholding sugars and starches must first be made. Judged by such tests, the alleged curative properties of such drugs as bromide of arsenic, ergot, opium, the salicylates, jambol, etc., would probably be estimated at a much lower value. The selection of cases no doubt affects greatly the statistics of those who have written upon the prognosis of this disease. Cantain says that diabetes is curable provided the treatment be begun early and continued for a long time. Professor Berussi says that he has never seen a case cured, and Seegen, among four hundred patients, never found one who was so much improved that he could eat carbohydrates like other people. Mr. Martineau, in a recent communication recommending lithiated arsenic, claimed to have cured 67 out of 70 cases ! Frerichs, discussing the treatment of diabetes (four hundred patients) says that cure is rare. He himself mentions 12 cures, and 250 deaths. Andral, among 84 cases, found that the sugar disappeared in a very small number of cases, and Lecorchi gives about the same opinion.

There can be very little doubt that well-established diabetes is almost, if not entirely, incurable. It may, however, run a very long course, and this is especially the case in diabetes of nervous origin and in those forms which occur during the later periods of life.

A SYMPOSIUM ON THE TREATMENT OF DYSENTERY.

"THE Treatment of Dysentery by some of the Leading Physicians of Texas" is the title of a medical symposium conducted under the auspices of the Texas *Courier-Record of Medicine*. A perusal of the various contributions under this head shows that the therapeutics of dysentery has not crystallized into any definite shape in the Lone Star State. One physician gives quinine, opium, and blue mass in repeated small doses for malarial dysentery ; salts and laudanum for that produced by indigestible substances ; in dysentery with ulcerated lower bowel, morphia and hydro-naphthol are thought indispensable. The ipecac plan is not found satisfactory. Another writer pins his faith on ipecac, giving it (after a purge) in twenty-grain doses, wetted with a drachm of laudanum. This dose is repeated on the next day, and again on the third day, if necessary. Hot fomentations to the abdo men and warm emollient injections, with quietude and proper diet, are also among the measures employed. In some epidemics quinine is the most important factor in the cure. Another contributor depends largely on ipecac, in thirty-grain doses, combined with morphia. This is, however, only in the early stages of the disease. Later, hot-water enemata, followed by hot injections of a twenty-five per cent. solution of fluid extract of hydrastis, are used, with rest and starvation. After the injections an opium suppository is given.

A fourth member of the symposium gives first a laxative consisting of two grains of calomel, followed by a saline. After this opium is given by mouth or anus, and opium is the drug chiefly trusted. At occasional intervals a dose of castor-oil is given.

A REMEDY FOR THE PLAGUE OF RABBITS.

A very large sum of money having been offered by the Government for some measure by which the rabbits can be exterminated from New Zealand and other neighboring colonies, M. Pasteur voluntarily contributes his plan for accomplishing this purpose. It consists in creating among the rabbits an epidemic of chicken cholera. This disease, according to Pasteur, affects rabbits as well as fowls, but does not harm any of the domestic animals. Pure cultures of the cholera-bacillus should be distributed over the rabbits' feeding-ground. The poison would be conveyed by them to the holes, and there would multiply faster than even rabbits can breed. The idea is a novel and bold—not to say cruel—one. The question whether the introduction of the poison of a new disease might not ultimately do more harm than good requires much consideration. Pasteur thinks that fowls could be protected by keeping them housed, or in yards. If M. Pasteur had ever raised chickens he would not, perhaps, think this so easy a matter.

The whole project is profoundly shocking to the sensibilities of *The Lancet.* Pasteur's proposal, it says, could hardly have originated in the mind of a medical man. It is "a misuse of medical knowledge," and is quite comparable to poisoning the wells in a hostile country.

Our contemporary would not, apparently, object to killing the rabbits with rat-poison, dynamite, or any legitimate explosive; but it recoils from using the bacillus of fowl-cholera.

CHRONIC HYPERSECRETION OF THE GASTRIC JUICE AND ITS TREATMENT.

Riegel regards the constant hypersecretion of gastric juice as a functional disorder in which this fluid is continually poured out, even into an empty stomach, and hence without the normal stimulus of ingestion. Most gastrological writers, not excepting such modern ones as Ewald, believe the morbid condition in question to be quite rare, although they admit the frequency of instances of simple hyperacidity. Riegel, however, holds that hypersecretion is of rather common occurrence, and in support of this view adduces the testimony of Jaworski and Gluzinski.

It would appear that many patients afflicted with hypersecretion become emaciated, anæmic, and even cachectic; so much so, indeed, as to prompt the suspicion of malignant disease. But in other cases hypersecretion may continue for years without the supervention of marked malnutrition.

In the diagnosis of chronic hypersecretion the external examination of the stomach affords only negative evidence, although dilatation is commonly found in cases of very long standing. Positive signs of the presence of this disorder may, however, be obtained by an examination of the undiluted contents of the stomach about five hours after a so-called test-meal. A large proportion of the ingested meal is generally found, and, on standing, two layers are formed, of which the lower, thicker one contains undigested starch, but scarcely any fibres of flesh. The stomach-contents are also abnormally acid, and it has been ascertained that hydrochloric acid is present largely in excess of the normal proportion. Riegel states that he has found as much as six per cent. in some of his cases. According to this observer, it is necessary, in order to make a positive diagnosis, to withdraw some of the contents of the stomach when no food is in it. To accomplish this, the entire contents may be removed at night and the stomach-tube used the following morning. If we are dealing with a case of the kind in question, then this early morning examination will yield quantities (from five to fifteen ounces) of a stringy, intensely sour fluid that responds to the tests for hydrochloric acid.

The symptomatology of this condition is not well defined. Indigestion is commonly observed. Acid eructations are frequent. Gastralgic paroxysms are apt to occur, but cases exist in which there is no pain. Vomiting of highly acid masses often takes place, and not a few patients have a constant craving for food. But in some patients there is loss of appetite; thirst is often increased. From all this, it is clear that chronic hypersecretion of the gastric juice does not in its subjective signs differ essentially from other gastric derangements.

As regards the treatment of this condition, Riegel advises systematic washing of the stomach, alkaline salts, more particularly the Carlsbad waters, and a dietetic regimen, consisting largely of albuminoid foods, in as dry a condition as possible. Starchy foods are, of course, to be eschewed as completely as possible. The only drug which has been found of value is opium, and this is to be exhibited in only moderate doses.

DISEASE-GERMS AND ENVIRONMENT.

In higher types of organisms sterility is the rule among hybrids. In the vegetable world this is different, and botanists recognize that fertile hybrids are very abundant in nature. Lichens, for example, form a fertile family, which sprung originally from an indiscretion between fungi and algæ. Many varieties of fungi are derived from elementary states of penicilium and oïdium; and it is known that there may be a variety of form amid particular pathogenic micro-organisms. There is much evidence to show that harmless micro-organisms may develop into disease-germs, and *vice versa.*

These facts have been adduced recently by Dr. E. M. Hunt, in order to show that the specific germ of disease is an elusive thing, and that, though in our search for it we get the form, the essence may still escape us. It will not be enough, he thinks, in studying pathogenesis to know the morphology and laboratory history of these organisms. We must investigate also the conditions in which the microbe developed during the prevalence of the disease it was supposed to cause. The bacteriologist's work is not alone sufficient, but must be supplemented by that of the physician and sanitarian. The question whether new diseases may not spring up, or whether there may not be certain conditions which give specific infective power to a micro-organism previously innocuous, may perhaps be settled in this way. Dr. Hunt presents the conclusions to his very suggestive paper in the following paragraphs:

1. The study of parasites, or germs, as they are called, is only one of the methods of informing ourselves as to the phenomena of disease, and in itself is not likely to be the key to rational and successful treatment.

2. Our attention should be directed, far more than now, to the study of conditions and circumstances under which new forms appear; to the influence of persons and surroundings, instead of to the mere finding of a specific form. The latter would, of course, be most valuable as one of the facts in the chain of evidence, but we should not, as now, seek so much to look to it as the cause of disease as to inquire what conditions have caused this or that particular microphyte to be present.

3. We should be able to account for the occasional occurrence of a disease independent of any previous case, and for changing types of disease and new diseases, and would come to treat diseases less by their names and more in view of their type and the effect of surroundings upon them.

4. The tendency of all this is to magnify the importance of close observation, and to lead us to feel that success in warding off disease, and in treating it when it appears, depends mostly upon close observation and that experience which is derived from actual practice.

THE SPONTANEOUS ORIGIN OF SCARLET FEVER DE NOVO.

The old question whether scarlet fever ever arises *de novo* has been started again by *Science* in a recent report on scarlet fever made by various health-officers and sanitarians to its columns. Dr. William K. Newton, the State Dairy Commissioner of New Jersey, writes:

"I have often seen isolated cases of this disease beginning at a time when no other case existed in the city. Many times I have seen a single case begin without any probability of an exposure to another case, but I do not think that we are justified in accepting the theory that the disease may arise *de novo* because of our inability to find the original case. But there is much to lead us to study this side of the question, for filth may be a possible cause."

Dr. R. B. S. Hargis, of Florida, writes:

"I have seen scarlet fever on two occasions, in an isolated house—no other cases in the city nor in the neighboring places—the source of which could not be traced to any focus of infection outside the walls of the dwellings in which the cases existed. I have also seen measles, a congener of scarlet fever, undoubtedly a contagious disease, spring up spontaneously, and spread from a single isolated place all over the city, thus apparently arising *de novo*. Upon careful and anxious inquiry in regard to the above-mentioned instances of spontaneous development of scarlet fever and measles in isolated places, I was informed that none of the parties in those houses had had any correspondence, by letter or otherwise, or purchased or received any fabrics, or indeed articles of any kind, from persons at a distance anywhere."

Dr. Samuel W. Abbott, of the Massachusetts State Board of Health, and Dr. G. C. Ashman, Health Officer of Cleveland, O., both are decidedly of the opinion that scarlet fever does not arise *de novo*. This is the general opinion of the profession. Yet many physicians can recall instances in which there seems to have been no possible way by which the disease could have been carried. Scarlet fever, however, while most amenable to quarantine, has a virus more tenacious and portable than that of any other infectious disease, unless it be smallpox. Hence this fever is often spread in an obscure and apparently mysterious manner.

PETTENKOFER AND HIS MOST RECENT VIEWS ON CHOLERA.

Pettenkofer, who is still by many regarded as a leading cholera "expert," but whose views are chiefly remarkable for their changeability, has recently proclaimed his acceptance, at least in a modified way, of Koch's doctrine. At the International Congress for Hygiene and Demography lately held at Vienna, an interesting discussion on cholera took place. Not a few of the delegates expressed their opinion to the effect that intercourse with cholera-infected persons or their belongings was not the only means of acquiring the disease, or spreading its contagion.

The condition of the soil was claimed by some, chief among whom, of course, was Pettenkofer, to play an important rôle in the spread of the malady. It is a pity that the views of these gentlemen did not get much beyond this vague notion about "something else" being necessary for the propagation of cholera besides a favorable soil for the development and multiplication of its specific microbe.

Pettenkofer himself, according to the *Medical Press*, stated that "he fully appreciated the value of bacteriology, and that it was his conviction that the etiology of infectious diseases would never arrive at its aim without bacteriological investigations. All the symptoms of cholera, however, could not be explained by the presence of the comma bacillus alone. Above all, we had to answer the question as to what was the behavior of cholera in its endemical home, in India; whether it had its point of departure in the patients affected with cholera or in the localities where cholera was present. We had an exact knowledge as to the frequency of cholera in India during the last twelve years. It was evident that the conditions of localities were of a decided influence on the spread of this epidemic, and the same was true of the influence of time. At Genoa, where nine epidemics of cholera had already taken place, the cholera period always lasted from July to November, whereas no single case of cholera occurred during the other months. He did not, however, wish to denounce bacteriological investigations by his opposition to the contagious theory; he only wished that we, at length, should abandon our narrow horizon, and that we should take into consideration also the conditions of place and time, without which the immunity of certain places against cholera could not be explained."

In reply to such reasoning, it seems scarcely necessary again to point out that the adherents of Koch have never disputed the influence of "place and time" in the production and propagation of cholera. The very life-history of the comma-bacillus was made clear only through an adequate recognition of these conditions.

It certainly appears strange that the views of Pettenkofer, who has changed his position so frequently with regard to the most vital points in the doctrine of the contagion of cholera, should still command the attention they do. Dr. McClellan has, long ago, clearly demonstrated the unreliable nature of the evidence upon which Pettenkofer built up his dogmas.[1] Nevertheless, with every advance in our understanding of the disease, Pettenkofer appears as a voluminous writer and indefatigable speaker in defence of his own peculiar notions, so modified as to accord in some measure with current doctrines. He has never added anything positive to our stock of knowledge, but he is ever ready, by opposing, to detract from the well-earned reputation of those who have. His latest attempt to bring his "subsoil" theory into harmony with Koch's doctrine cannot be regarded in any other light than that of a complete failure.

THE DEATH-PENALTY BY ELECTRICITY.

MESSRS. ELBRIDGE T. GERRY, Alfred P. Southwick, and Matthew Hale, Commissioners appointed by the Governor to investigate and report upon the most humane and practical method of carrying into effect the sentence of death, have made their report, after a year's examination of the subject. They investigated the history of the various methods of applying the death-penalty, and come to the conclusion that garroting and the guillotine are too brutal, and that hanging is clumsy and uncertain. They recommend, in conclusion, the use of electricity. Electric-light wires are to be tapped, the convict is to be placed in a chair with an electrode at the head and feet, and the connections made. The electrical current, we are told, somewhat naively, "is one hundred times swifter than nerve-force," hence, perhaps, its malignant effect. (Nerve-currents travel at the rate of about one hundred feet, electrical currents at the rate of from eighteen thousand to two hundred and eighty-eight thousand miles, a second.)

The Commission evidently recommend for the death-penalty, not currents of high potentiality and small quantity, like lightning-strokes, but currents of great strength and quantity. The practical question will be, whether such currents can be made to destroy life without burning or disfigurement. On this point perfectly satisfactory evidence is not furnished, so far as we can learn. It is easy to stun a man with a current of a few ampères strength, but to destroy life instantaneously, without cauterization, is more difficult. The human system can withstand violent shocks and heavy electrical discharges, for it is protected by non-conducting integument. The resistance of this will have to be diminished by wetting the feet, perhaps shaving the head, and by fastening the criminal tightly to the electrodes. Altogether, the technical difficulties of killing a man with electricity, *tuto, cito, et jucunde*, are considerable, and apparently have not been by any means completely studied out by the learned Commission.

ALCOHOL AS A FOOD.

IN the controversy over alcoholic beverages, which is becoming so acute and which has already assumed the proportions of a political question, the distinction between alcohol as a beverage and alcohol as a therapeutic agent is in danger of being lost sight of. With the question, as far as it is a political one, THE MEDICAL RECORD has nothing to do. It is, of course, opposed to the intemperate use of alcohol, just as it is opposed to everything that is injurious to health, but it cannot enter the field of controversy upon the question of how best to prevent this abuse. The political enemies of alcohol are not, however, we regret to say, willing to confine themselves to their own field; they see no good whatever in spirits of wine, and they decry its therapeutic worth as fiercely as they oppose its social consumption.

There is one fact, especially, the statement of which seems always to act as a most powerful nervous excitant upon the organisms of these somewhat intemperate friends of temperance. This is, that alcohol is a food. We have been taken to task, recently, for an allusion to this fact, by an esteemed correspondent, who writes, under date of January 2d, as follows: "Your somewhat oracular paragraph in last issue of your journal touching alcohol as food is, I think, open to criticism. Is it not a fact that alcohol only *temporarily* arrests or, more correctly, slows the waste of the body, just as tobacco, coca, and opium do? Are these also, on that account, foods? Prove, if you can, that a single atom of alcohol ever enters into the *making up of tissue* and your position is won. It may be true that a small moiety of the alcohol, some of its carbon molecules, are oxygenized, but if that constitutes food it is on the homœopathic side."

The mistake that our correspondent makes, and he is not alone in his error, is in regarding food simply as material concerned in "the making up of tissue," and in ignoring the fact that fats and carbohydrates are just as certainly food as are the proteids. The non-nitrogeneous principles are as necessary to the preservation of life and the production of force as are the nitrogeneous, and we can no more exist without the one than we can without the other. Preservation of animal heat is as essential to life as is the building up and repair of tissue, and the one and the other are accomplished in the same way, by the oxidation of the alimentary principles in the system.

Now, having defined food and having stated what are its chief uses in the economy, let us see what becomes of alcohol when taken into the system. It is not true that "a small moiety" only of the alcohol ingested is oxidized in the economy. On the contrary, the greater part of it disappears, and not more than sixteen per cent. escapes unchanged in the excreta. Many experimenters, indeed, put the amount so excreted as low as three or four per cent. The remaining eighty-four to ninety-seven per cent. is consumed within the body, and during its oxidation heat is evolved to maintain the normal animal temperature. By a process of oxidation the alcohol is converted into aldehyde and acetic acid, and is finally split up into carbonic acid and water, according to the following formulæ (Binz):

---

[1] Vide A Treatise on Asiatic Cholera, by E. C. Wendt, M.D., pp. 139 to 143. W. Wood & Co., 1885.

1. $C_2H_6O + O = H_2O + C_2H_4O$ (aldehyde).
2. $C_2H_4O + O = C_2H_4O_2$ (acetic acid).
3. $C_2H_4O_2 + 4O = 2CO_2 + 2H_2O$.

If the more readily oxidizable alcohol is not present, the fats must be burned to supply the animal heat which is continually being lost by radiation. Alcohol, therefore, serves the same purpose as the other carbohydrates, the sugars and starches, in producing the heat and in this way preventing in a measure the consumption of fats, and also of the nitrogeneous principles, thus permitting of their being stored up in the tissues. And if it acts in the same way as food acts, not necessarily in building up the tissues directly, it must be regarded as a food. And it is a food.

These are, we know, elementary facts with which most of our readers are familiar, but we cannot hear physiological principles denied without attempting to reassert them, even at the risk of wearying the well informed. And, indeed, we feel, in this instance, that we are helping the cause of temperance in so doing. Advocates never help their cause in the long run by denying facts. Misstatements are like boomerangs, and the more there are of them the more numerous are the wounds of those that make them. We agree with the prohibitionists that, as Parkes says, "If alcohol were unknown, half the sin and a large part of the poverty and unhappiness in the world would disappear;" but we do not agree with them when they assert that alcohol is an unmitigated curse to mankind. Alcohol, when properly used, is a great blessing, and it has saved countless numbers of human beings who have lived to cheer the existence of others, and to add greatly to the sum of human happiness and to the advancement of our race.

THE NOSE THE SOURCE OF ALL OUR WOES.

At the last Congress of German Naturalists and Physicians, held in Wiesbaden, Dr. Gacy reported several cases of mental disturbance characterized by an impossibility of fixing the attention on any subject, except for a very brief period, or of prolonged mental effort of any kind whatever. This condition, to which the author gave the name of aproxia, was always associated with certain lesions of the nasal mucous membrane and obstruction to the passage of air through the nasal fossæ.

This is, we believe, the latest accusation which has been brought against the sinful nose. Headache, cough, dyspnœa, earache, neuralgia, hay fever, acne, convulsions, and syncope are only a few of the many evils which this troublesome organ is accused of having inflicted upon long-suffering man, and it bids fair to outstrip even the ovaries as a centre for morbid reflexes. As regards aproxia, however, it is said not to be a reflex, and the mechanism of its production is assumed to be a purely physical one. The lymphatic spaces beneath the dura mater have been found to be in direct communication with the mucous membrane of the nasal fossæ, and inflammation of the latter is supposed to interfere with the elimination of the waste products resulting from cerebral activity, thus leading to mental sluggishness. But whatever may be its methods, the nasal organ is evidently responsible for many, if not most, of our ills. Clearly, the nose must go.

News of the Week.

Contributors will confer a favor by writing the name and address on the first page of their communications, directly under the title. When the name and address are sent in a letter, the latter is liable to become separated from the manuscript, and then we have no clew to the author's name, and are unable to communicate with him when necessary.

The Dietetic Gazette is the new name of the former *Journal of Reconstructives*. Dr. George B. Fowler is the editor of the periodical, which is apparently devoted to physiological medicine in its widest sense. The first number makes a very creditable appearance, containing a variety of information, chiefly of a practical kind.

The Medical Record Does not Prescribe for Correspondents.—We are so constantly receiving letters from laymen for medical advice that it is necessary to state that we never prescribe for such patients, nor do we ever recommend or pass opinions upon the merits of practitioners, drugs, or apparatus. Proper advice on all these matters can be easily obtained by consulting the family physician and honestly paying his fee.

Dr. R. Van Santvoord, of this city, calls our attention to the following misprints in his recent article: Page 36, first column, last paragraph, lines 5 and 14, contains the following: "This case suffered from neuralgic pains in *anus*," and "a symptom-complex resembling progressive muscular atrophy developed in the *anus*." Instead of *anus*, both should have been *arms*. Page 36, second column, fourth paragraph, fourth line, *venous reflex* should read *venous reflux*.

Dr. John F. Ridlon has been appointed attending orthopedic surgeon to St. Luke's Hospital *vice* Dr. N. M. Shaffer resigned.

In Honor of the Lady.—A short time ago a lady in Mexico, the first of her sex in that country to attain to such a dignity, was graduated in medicine. In order fittingly to celebrate the great event, her fellow-students in the medical school organized an amateur bull-fight in her honor.

Grindelia Robusta in Pertussis.—The *Paris Médical* publishes a communication from M. Bilhaut (read at the Société de Thérapeutique) on the action of grindelia robusta in whooping-cough. The grindelia robusta is a perennial plant indigenous to Mexico and California. The active principle is a resinous substance possessing antispasmodic properties, and at the same time stimulating the mucous membrane. It is efficacious in bronchitis, and also in chronic cystitis. It is eliminated by the kidneys. The tincture, fluid extract, or syrup of grindelia robusta, in cases of whooping-cough, stop vomiting and the other painful symptoms, and transform severe whooping-cough into a mild affection of short duration. The dose is one gramme to four grammes a day for adults. For children the tincture is preferable. M. Bilhant cites ten successful cases.—*British Medical Journal.*

WHY DO THEY?—"Senex" writes: "Apropos of the remarks on left-handedness in your issue of December 24th, I should like to see a satisfactory explanation of the fact that women always (with exceedingly rare exceptions) button from right to left, and men from left to right. Personally I have remarked only four cases of exception to the rule."

DR. GEORGE A. PETERS has resigned as attending surgeon to St. Luke's Hospital, and has been appointed on the consulting staff.

OFFICERS ELECTED FOR THE NEW YORK PATHOLOGICAL SOCIETY.—The following officers of the New York Pathological Society were elected at the meeting of January 11, 1888: *President:* William P. Northrup; *Vice-President:* Frank Fergusson; *Secretary:* Walter Mendelson; *Treasurer:* J. H. Hinton; *Editor:* J. C. Peters; *Committee on Admission and Ethics:* J. C. Peters, W. H. Porter, J. Emmet Holt, J. West Roosevelt, George R. Lockwood, Jr.; *Members of the Publication Committee:* George C. Freeborn, W. R. James.

DR. JOHN A. MCCREERY has been appointed physician to the St. Vincent's Hospital, New York.

DR. FRANK T. PATTERSON.—By an error we announced the death of Dr. F. T. Potter, of Petersburg, Va., in THE MEDICAL RECORD of the 7th inst. The name should be Patterson.

IMPROVEMENTS IN THE STAFF OF THE CITY LUNATIC ASYLUMS.—We are glad to learn that, as the result of the recent agitation over the subject of our city insane asylums, a larger and much needed sum of money has been appropriated for their maintenance. Instead of having a medical staff at each asylum one-half of whose members served without pay, while the others received salaries ranging from $250 to $800, *all* the members will now be paid, and the salaries will range from $300 to $1,200. It is believed that when these facts are known, a better class of men will apply for positions than was formerly the case. The improvements in the matter of the medical staff will apply to all other branches of the asylum administration.

THE INSANE OF NEW YORK, THEIR CARE, AND MEASURES FOR THEIR COMMITMENT.—The twenty-first annual report of the State Board of Charities gives the number of insane persons in the institutions of this State on October 1st last, as 14,062, an increase in this class over last year of 524. Much of this increase in the number of insane is declared to be due to immigration. The Board advocates amendments to the Federal law regulating immigration. The article of the report relating to the commitment and detention of the insane recommends the following legislation: First, directions for commitment on certificates of the physicians in the case at the outset shall be by court decree, after examining the person in question, under provisions similar to those of the State of Massachusetts. Second, more absolute provision for the discharge of patients by the Commissioner of Lunacy, by procedure similar to that of the State of Pennsylvania. Third, the enactment of a provision of the Scotch lunacy law requiring the superintendent of every asylum for the insane yearly to make affidavit that one month prior he has reviewed the cases of all patients in custody, and that their continued detention in an asylum is necessary for their welfare or the public safety.

JURY TRIALS IN LUNACY CASES.—The Society for Promoting the Welfare of the Insane has caused a bill to be prepared for presentation to the Legislature of this State, which provides that no person alleged to be insane shall be committed to any lunatic asylum, public or private, until a jury shall have declared such person to be of unsound mind. Such a process would be clumsy, expensive, and dangerous, and is quite uncalled for.

THE DEATH OF M. ACHILLE FOVILLE is announced. The deceased was son of the celebrated author of "Traité complet de l'Anatomie et de la Pathologie du Système nerveux," and he was himself well known for his contributions to neurology and psychiatry.

CLUB DOCTORS AND DRUGGISTS' PERCENTAGES.—A correspondent writes us, calling our attention to an abuse that exists in connection with the numerous club and society doctors in this city. The number of organizations among the poorer classes, which hire a doctor to treat the families of members, is considerable. The pay, in comparison with work demanded, is a mere pittance. It is charged that many increase their small salaries by getting a percentage from the druggist, and that they prescribe an enormous amount of medicine in consequence. Our correspondent was shown seven bottles of various kinds of medicines, all ordered for one poor patient within thirty-six hours. We should be glad to learn that he is misinformed.

DR. JAMES R. NICHOLS, of Haverhill, Mass., died on January 2d. Dr. Nichols was well known, especially in New England, as founder and editor of the *Journal of Chemistry*, now the *Popular Science News*. He was sixty-nine years of age at the time of his death.

A THEORY OF OBESITY, proposed by M. Leven recently, and described before the Société de Biologie, is that it is a nervous disorder, and to be treated by avoidance of mental and physical fatigue, and a diet of eggs, soup, milk, rice, and potatoes.

BEQUESTS TO HOSPITALS.—By the will of the late William Hilton the Massachusetts General Hospital gets $50,000, the Boston Dispensary $50,000, and the Children's Hospital $20,000.

MORALS AND ART.—Mr. Anthony Comstock, as agent for the Society for the Suppression of Vice, has seized and destroyed forty-five thousand nine hundred and forty-three obscene pictures, circulars, songs, etc., and fifty-six articles of indecent or immoral use.

DECLINE OF MARRIAGE AND INCREASE OF PROSTITUTION.—According to statistics collected and reviewed in the *Pall Mall Gazette*, prostitution is gradually elbowing matrimony out of the field. The falling off in the proportion of marriages per 1,000 is shown here :

	England.	Scotland.	Ireland.	France.	Belgium.
1866	17.5	14.7	10.8	16.0	15.7
1861–80	16.4	14.2	9.8	15.8	14.6
1886	14.1	12.4	8.4	14.8	13.4

	Denmark.	Switzerland.	Austria.	Germany.	Holland.
Average 20 years	15.3	15.1	17.1	17.4	16.2
1886	14.2	13.7	15.5	15.8	13.9

The mean age at which marriage occurs has also been steadily rising since 1873. In 1886, it was 28.2 for men and 25.9 for women. The decrease in, and postponement of, marriage, mean increase in prostitution. For no one maintains that the average man of late years has become more ascetic than formerly. The figures above given apply to Europe. They may in a measure be accounted for by the emigration of people at the marrying age.

MYOPIA AND SCHOOL BOOKS.—A decree has just been issued by the Austrian Minister of Public Instruction, forbidding the use of books printed with small type in public schools, as shortsightedness is so prevalent among school-children in Austria.

A VERY SEVERE ATTACK ON THE CHICAGO MEDICAL SOCIETY appears editorially in the *Medical Standard*, which able but acid periodical says : "The Chicago Medical Society is undeniably in a decadent state. The greatly diminished attendance on its meetings is sufficient evidence of this. The reasons are self-evident. The packing of the discussion by the president, the inexcusable indictment of a conscientious investigating committee at the dictation of the 'boodlers' whom they exposed, the servility displayed toward rascally county officials by the chief official, the toadying to local diploma-mills, have all played their part. The society needs to redeem itself from its present decadence by encouraging more critical discussions, by an impartial enforcement of the five-minute discussion rule, and by tolerating less dictation by members of unsavory political and diploma-mill affiliations. The society should take a more active part in enforcing the Medical Practice Act, the Abortifacient Act, and in securing medical control of the county institutions. These topics are better worth attention than the lucubrations of germ-crammed men using their recent voyages to Europe as a personal advertisement."

ANTIPYRIN, now so largely prescribed, according to M. Robin, diminishes the total amount of urine and urea, and increases the uric acid. As it lessens the nervous excitability, it increases the elimination of phosphorus incompletely oxidized. Antipyrin lessens tissue-metabolism.

MR. LAWSON TAIT is reported to have been appointed Professor of Gynecology in Queen's College, Birmingham.

CALOMEL AND SANTONIN.—A physician in Atlanta, Ga., was last year prosecuted for homicide for administering to a child a dose of five grains each of calomel and santonin. After a full investigation and the introduction of numerous expert witnesses, the prosecution failed.

A NEW HOSPITAL, for colored people, is to be erected in Atlanta, Ga.

"THE ONE-LUNG COUNTRY" is the name popularly given to Southern California.

JABORANDI IN ERYSIPELAS.—Since he has used jaborandi in erysipelas, Dr. Waugh considers that disease of little significance, having had no difficulty whatever with a case of it for two years. He gives twenty drops of the fluid extract every two hours, until perspiration sets in. If the erysipelas shows a tendency to recur, the use of the drug is resumed.

CHICAGO AS A MEDICAL CENTRE.—A correspondent of the *Boston Medical and Surgical Journal* calls attention to the claims of Chicago as a medical centre. It has eleven medical colleges, over one hundred professors, a medical library is being started, and endowments for medical research are expected in time.

EPIDEMIC OF CRAB-LICE IN ST. LOUIS.—The Queen City of the West has successfully avoided cholera and has no small-pox, but, according to the *St. Louis Medical and Surgical Journal*, has been suffering from several small epidemics of crab-lice. The *Journal* says : "A number of the gentlemen so affected did not deem it prudent to advance the water-closet theory to their physicians, as this hypothesis is generally looked upon with more or less suspicion. A circumstance, however, arose which shed considerable light upon the origin of one little outbreak. Four or five gentlemen, some connected with a hotel, the others guests, all called upon one physician for treatment. A search being instituted, it was discovered that the hotel water-closets were infested with the little pests. In fact, one closet was literally alive with the vermin. It may be mentioned, *en passant*, that women are very apt to acquire crab-lice by sweeping them up with their skirts, and this most often in street-cars." In this connection, we clip from an exchange the following : "Crab-lice (pediculi pubis) are said to be immediately destroyed by washing the parts with ether."

OCULAR SYMPTOMS OF EPILEPSY.—The examination of a thousand cases of epilepsy by Dr. Gowers revealed but one morbid condition of frequent occurrence in the ocular fundus, and that was an unnatural equality of the size of the arteries and veins of the retina. Dr. Charles Oliver, of Philadelphia, has frequently observed a reduction of the visual fields for form and color, a granular condition of the choroid in the macular region, a dirty, red-gray degeneration of the optic nerve, and a thickening of the fibrous tissue of the retina.—*Lancet.*

Reports of Societies.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 14, 1887.

T. MITCHELL PRUDDEN, M.D., PRESIDENT, IN THE CHAIR.

DR. R. W. AMIDON presented, in behalf of a candidate, a specimen of *congenital diaphragmatic hernia.*

DR. HODENPYL presented, for a candidate, a specimen of *epithelioma of the cervix, with suppurative nephritis.*

DR. W. H. PORTER presented, in behalf of a candidate, a specimen of *incapsulated cerebral abscess, secondary to a pistol-wound.*

DR. H. P. LOOMIS presented a specimen of

PRIMARY TUBERCULOSIS OF THE KIDNEY,

with the following history: The patient was a man, thirty-two years of age, who was admitted to Bellevue Hospital, November 17, 1887, after a protracted debauch. His mother died of phthisis. He had had gonorrhœa, but there was no history of syphilis. He had suffered from gastric disorders, due to alcoholism. Six years ago he had pneumonia, and one year later rheumatism. About six months ago, after a protracted spree, he had an attack of what was diagnosticated as "acute Bright's disease," but he says he made a good recovery. About November 17, 1887, he began to have fever, and his temperature was 101° F. His abdomen began to enlarge, there was swelling of the feet, his urine contained albumen, was scanty in quantity, dark-colored, and loaded with urates; there were no casts, but some blood and pus. Bowels constipated, and skin slightly jaundiced. On November 19th he began to have cough, his difficulty of breathing and fever increased, and the physical signs led to the diagnosis of general bronchitis. He grew worse rapidly, and died on December 2, 1887, with increased anasarca and jaundice.

At the autopsy the abdominal cavity contained a large quantity of straw-colored fluid. The heart and pericardium were normal. The left lung was generally adherent; the right lung was firmly bound to the chest-wall in places. On section the lungs were found to be studded with minute, elevated, yellowish nodules, from the size of a pin's-head to a small pea. The bronchial glands were enlarged and pigmented. The left kidney was enlarged, but otherwise normal. The liver weighed seven pounds, and was cirrhotic and fatty.

The cæcum and ascending colon were adherent to the right ureter and kidney, and showed numerous broad tubercular ulcers nearly to the transverse colon. The edges of the ulcers were everted and thickened, and their bases presented a grayish appearance.

The kidney was enlarged, the capsule was non-adherent. The pelvis was dilated; the pyramids were nearly destroyed by the formation of irregularly shaped cavities which also had encroached upon the cortical substance. These cavities had ragged walls and contained yellowish caseous material. Throughout the cortical portion there were scattered small nodules which, microscopically, showed cheesy centres surrounded by an area of lymphoid cells, with numerous giant-cells.

The walls of the ureter were greatly thickened, and infiltrated with tubercles. The walls of the bladder were thickened, and the mucous membrane presented the appearances usually seen in chronic vesical catarrh, but there was no tubercular infiltration.

He regarded the case as one of primary tuberculosis of the kidney; or, better, perhaps, tubercular pyelonephritis.

It was interesting to observe how the tubercular process extended to the intestines, and, lastly, to the lungs, manifesting itself in an eruption of miliary tubercles. Another point of interest was the fact that only one kidney was involved.

DR. LOOMIS also presented a specimen of

CONGENITAL CYSTIC DEGENERATION OF THE KIDNEY,

removed by Dr. W. M. Polk from a female child, aged twenty-two months. An enlargement in the right side of the abdomen was first noticed when the child was eight months old, which was painless, and produced no symptoms subsequently except shortness of breath from pressure upward. The child was well nourished. The mass in the abdomen extended from the pelvis to the free border of the ribs upon the right side, and beyond the median line to the left.

Dr. Polk made an incision, three inches long, in the median line, below the umbilicus. It was then found that the tumor was adherent to the vermiform appendix and transverse colon, and that it was behind the peritoneum.

The abdominal incision was enlarged to within one inch of the ensiform cartilage, and the tumor brought out through the opening, when it was found that it had a pedicle about two inches in diameter. The peritoneal covering was incised and peeled off from the growth, and several adhesions were ligatured and cut. The peritoneal covering was stitched to the abdominal wall with catgut sutures, and the incision was closed with silk-worm gut, after introducing a large drainage-tube. The child reacted partially from the chloroform, but died from shock two hours after the operation. The left kidney was apparently normal. There was neither uterus nor ovaries.

The mass weighed five pounds, had irregular shape, and was enclosed in a dense fibrous capsule that sent prolongations inward. The contents consisted of an immense number of cysts, varying in size from those which were microscopical up to the size of an olive.

Microscopically the contents of one of the cysts showed a collection of epithelioid cells that presented the appearance of a uriniferous tubule. Another cyst showed a tuft of capillary vessels which were regarded as part of a Malpighian body.

DR. REGINALD H. SAYRE presented a

DISSECTING-ROOM SPECIMEN OF MORBUS COXARIUS.

The disease had not been diagnosticated, and the case had been recorded as one of myelitis. There was no external sinus. There was rupture of the capsule of the joint, with extravasation of pus and perforation of the acetabulum. No pus was found in the rectum. The disease was chiefly acetabular, and the head of the bone was in its normal position. In the seventy-four cases in which his father had performed exsection, the head of the bone had not been out of its place, and he had therefore concluded that the so-called *dislocation* of the third stage of hip-joint disease was due to rough manipulation.

DR. HODENPYL presented a heart that showed

ACUTE PERICARDITIS, WITH THE PRODUCTION OF FIBRIN AND PUS.

There was no history of the case. At the bottom of the pericardial sac was a thick layer of cheesy material. The inner surface of the pericardium and the outer surface of the heart were covered with a thin layer of fibrin.

Dr. Hodenpyl presented a second heart, that showed

CHRONIC ENDOCARDITIS.

The organ was about normal in size. The tricuspid valve was greatly thickened, and it was on that account especially that the specimen was presented. The only history was that the woman was brought into the hospital with extreme dyspnœa and cyanosis, and died soon afterward.

Dr. Hodenpyl presented a third heart, which showed

MARKED HYPERTROPHY AND DILATATION, WITHOUT FATTY DEGENERATION OF THE MUSCULAR FIBRES.

The cavity of the right ventricle was very much enlarged, and the cavity of the left ventricle to a less extent. The kidneys showed the lesions of chronic diffuse nephritis. The heart was about twice its normal size.

Dr. Van Santvoord said that the absence of degeneration of the cardiac muscle was worthy of notice. He thought it was generally believed that when there was heart failure from any cause, degeneration of the heart muscle was commonly present, but he believed that the contrary was quite often the case, and that when from the clinical history of the case there was manifest heart failure, post-mortem frequently showed that there was no lesion of the muscle itself.

Dr. W. H. Porter directed attention to

PERFORATION OF ALL THE CUSPS OF THE AORTIC VALVE

in the specimen presented, and said that according to his experience similar openings were present in forty per cent., at least, of aortic and pulmonary segments. He had seen these perforations as early as the second or third year of age, and believed them to be congenital defects. He thought the specimen was one of those hearts which illustrated that the physical signs of aortic regurgitation might occur without the rational symptoms of that lesion.

Dr. Van Santvoord remarked that the openings referred to he had frequently seen, and, as in the specimen presented, they had been immediately under the very edge of the leaflet. It certainly seemed to him that they would not prevent complete closure of the valve, as they were above the line of contact when the cusps were brought together.

The President asked Dr. Porter if in the percentage of cases he had mentioned there was corresponding cardiac hypertrophy.

Dr. Porter replied that the amount of hypertrophy depended upon the size and number of the openings. If they were large there would be some hypertrophy, but in many cases he had seen the diagnosis of aortic regurgitation made and had found only this physical condition at post-mortem to explain it.

Dr. Van Santvoord thought that if this condition existed in as high as forty per cent. of hearts, evidence of regurgitation at the aortic orifice should be more common than it was.

The President said that he had examined the heart with Dr. Hodenpyl, and it had seemed to him that the perforations were so small and so near the edge of the leaflets that they would be covered when the valve was closed, and that the kidney lesion was the more plausible explanation of the hypertrophy.

Dr. Van Gieson presented an

ABSCESS OF THE LIVER

which was interesting chiefly because during life there was tympanitic resonance over the sac which made it appear that the liver was reduced in size.

Dr. Van Gieson also presented a specimen of

ANGIO-SARCOMA OF THE LUNG, WITH CALCIFIC DEPOSITS,

removed from the body of a middle-aged woman who had an amputation at the knee five years ago for a tumor which was not diagnosticated.

One of the lungs contained a few whitish nodules, some partially calcified, varying in size from a few millimetres to two or three centimetres in diameter. At the apex of the lung there was a nodule larger than the others (five centimetres in diameter), and more markedly calcific.

Microscopically the nodules consisted of areas which presented the characteristic appearance of angio-sarcoma, and of other areas made up of connective-tissue trabeculæ, partially calcified, enclosing oval and polygonal cells.

Dr. L. Emmett Holt presented a tumor of the umbilicus which he regarded as

A PERSISTENT MECKEL'S DIVERTICULUM, COVERED WITH MUCOUS MEMBRANE.

Dr. J. S. Thacher presented an

ANEURISM OF THE THORACIC AORTA.

The patient did not have any special symptoms, except some epigastric pain, and was treated for colic. There were found nearly two quarts of coagulated blood in the connective tissue outside of the aneurismal sac. The heart showed a very large papillary muscle, which illustrated an occasional cause of cardiac murmur.

Dr. Lewis Hall Sayre presented a specimen for which he was indebted to Dr. McKahn. It consisted of

THE HEAD AND NECK OF THE FEMUR,

removed by operation from a boy, five years of age, with good family history, who, three years ago, was taken with disease of the right hip-joint, from which he recovered with anchylosis in about eighteen months. Afterward an attempt to break up the adhesions was followed by inflammation, and in about six weeks an abscess made its appearance on the outer aspect of the thigh. At that time the limb presented the deformity usually seen in the third stage of hip-disease. The abscess was opened and drained, and it was then found that there was an abscess on the inner aspect of the thigh, and when that was opened the finger could be passed through the capsule, and the characteristic gelatiniform material readily removed.

Exsection was performed last Thursday by Dr. McKahn. The periosteum was very much thickened, and had considerable new deposit of bone in it. The operation was performed antiseptically, and the patient was doing well. The gelatiniform substance had been submitted to Dr. Biggs for examination, with reference to tubercle-bacilli.

The President presented a specimen of

RUPTURE OF THE HEART THROUGH THE RIGHT VENTRICLE, AS THE RESULT OF GENERAL FATTY DEGENERATION FROM ATHEROMA OF THE CORONARY ARTERIES.

For the epitomized clinical history he was indebted to Dr. W. N. Hubbard, House Physician, First Medical Service, Bellevue Hospital.

A woman, forty-five years of age, had been under treatment for Bright's disease some months ago. She had then complained of "trouble with her heart," and had not been well since. A couple of days before admission to the hospital she became worse; had shortness of breath and a sense of oppression about the heart.

She was admitted on December 7th, in the forenoon, cyanosed, with cold extremities, delirious, restless, and very thirsty. Respiration, 34; pulse, 150, and very irregular and feeble; temperature, 100.6° F. She was unable to sit up, but when propped up by a head-rest the dyspnœa and cyanosis were somewhat relieved. She complained of great pain about the heart. The chest-resonance was good; there were many coarse râles. The area of cardiac dulness was increased; no murmurs could be heard.

She slept a little at intervals during the following night, but was most of the time very noisy and restless. She seemed to develop œdema of the lungs, and died about twenty-four hours after admission.

Autopsy.—The body was well nourished, pale, lips blue. General appearance of abdominal cavity and viscera, normal. Right pleural cavity empty; left contained about five hundred centimetres of bloody serum.

Heart.—Area of exposed pericardium very large. Pericardial sac contained about five hundred centimetres of fluid blood. When this was removed a small triangular opening was seen near the apex of the right ventricle, through which oozed dark fluid blood. This opening communicated directly with the cavity of the right ventricle. The cavities of the right heart contained fluid blood, and voluminous, soft, ragged red clots, entangled among the papillary muscles, and adherent to the walls; valves normal. The left ventricle was firmly contracted, and the left cavities were moderately dilated and nearly empty. The mitral valve was moderately thickened and contracted at the edge, and the attached chordæ tendinæ were shortened. The walls of the coronary arteries were everywhere moderately atheromatous and fatty; but not especially so in the branch supplying the region of rupture. The entire heart muscle was pale and flabby. A small triangular tongue of heart muscle lay valve-like across the opening at the seat of rupture. Microscopically the heart muscle, in all parts of the organ, was the seat of marked, though not excessive, fatty degeneration and chronic interstitial myocarditis; but the fatty degeneration was not more marked at the seat of rupture than in other parts of the heart. The aorta was, throughout, the seat of extensive atheroma and fatty degeneration, and showed patches of calcification.

Lungs.—Both showed emphysema, chronic bronchitis, and moderate œdema, while in both lower lobes, posteriorly, were several hemorrhagic infarctions, from the size of a filbert to that of a small hen's egg. In the branches of the pulmonary artery leading to the two of these infarctions which were dissected, dense, occluding fibrinous clots were found.

All of the abdominal viscera were congested; while, developed to a moderate degree, were found the lesions of chronic interstitial hepatitis and chronic diffuse nephritis, the kidneys being slightly atrophied.

The case appeared to him of interest because the patient apparently lived for several hours after the occurrence of the rupture; because the rupture was at the apex of the right, and not of the left ventricle, as is more usually the case; and finally, because the rupture was that of a universally fatty heart, and not due to a circumscribed muscular lesion, dependent upon a local obstruction of a branch of the coronary artery, as it had been in most, if not all, of the ruptured hearts recently presented before this Society.

Dr. John C. Peters had presented a similar specimen several years ago, from a man forty-five years of age, and in whom there had not been any sign of cardiac disease until an attack of angina occurred. In that case there was almost complete occlusion of one coronary artery.

The Society then went into executive session.

Pajot on Sterility.—Speaking on the subject of the obstacles to fecundity in the human species, Professor Pajot says: "Has the woman an anteversion? Say to her: 'Have the kindness, if you please, every evening when you expect to have intercourse with your husband, not to urinate for five or six hours. Don't ask why; that doesn't concern you. Only don't urinate. You wish to have children? Yes? Well, then, urinate after intercourse, and not before.' If she has a retroversion, say to her: 'Madame, when your menses are over, eat plenty of eggs and plenty of rice. Take every night for three or four days a little pill which I am going to give you.' (This little pill contains simply a third of a grain of extract of opium.) 'Manage not to go to stool for three or four days. Then have intercourse with your husband, but don't go to stool till afterward.' You will say that all this is very ridiculous; yet the whole process is entirely rational and is based upon anatomical and physiological principles."

For Sweating of Hands.—Eau de Cologne, ℥ iv.; tincture of belladonna, ℥ ss.; rub the hands two or three times a day with this solution.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE DEBATE ON COW DISEASE AND ITS RELATION TO SCARLET FEVER IN MAN—TWO HOSPITAL DISPUTES—DEATH OF DR. ARTHUR FARRE—A SURGEON'S STETHOSCOPE—A MEDICAL CENTENARIAN.

London, December 30, 1887.

A special meeting of the Pathological Society was held recently, to discuss the nature of the disease which has made its appearance among the cows at Hendon (near London) and the alleged relation of this disease to the occurrence of scarlet fever in man. Important as were the issues raised, the debate cannot be said to have done much toward settling them. I can only briefly refer to some of the more important points. The debate was based upon a paper by Professor Crookshank, of King's College, in which he expressed the opinion that the cow disease at Hendon was really cow-pox. His opinion, however, was based upon the study of the disease, not at Hendon, but elsewhere. It was urged that the cow disease studied by Professor Crookshank was not identical with that occurring at Hendon, and that in assuming it to be identical with the Hendon disease he had been misled by the published descriptions of the latter. Dr. Klein strongly opposed the view that the two diseases were the same, and certainly scored a point against Professor Crookshank by pointing out some very minute bacteriological differences between the two affections. He had not, however, seen Professor Crookshank's cases in the early stage, and Professor Crookshank had not seen the Hendon cows at all. Professor Crookshank's view that the disease he had himself seen was cow-pox was not seriously questioned, but the evidence he brought forward tending to show that it is tolerably common, and, in fact, identical with what is termed by farmers "cow-pox," will surprise many who, like Dr. Buchanan, have been for years on the lookout for genuine cow-pox. One point which came out incidentally in the course of the discussion was that our metropolitan dairies are less insanitary than many country ones. Professor Brown remarked that, since he had entered on the present inquiry, fresh country milk had ceased to have any attractions for him. The question of the transmissibility of scarlet fever from the cow to man cannot be said to have been at all advanced by the recent debate. Professor Brown cogently observed that Mr. W. H. Power's report on the cow disease at Hendon, and its supposed connection with an epidemic of scarlet fever, was based chiefly on negative evidence—viz., on the fact that no communication of scarlet fever by human agency could be traced. So far as his own observations of the cow disease went, it had not been connected with scarlet fever, though an extensive epidemic of the latter existed concurrently. It was curious to note that milk from the affected dairies went into the very districts where no scarlet fever ensued. With such a large epidemic such a coincidence might have been expected, but it did not occur.

Two hospital disputes are in progress at present. One of these is at St. John's Hospital for Skin Diseases. This institution has long had an unenviable reputation for wrangles, and the late Erasmus Wilson, who once held the post of consulting surgeon to it, withdrew from it in disgust. It appears that the Committee of Management have been carrying matters with a high hand, and conducting the hospital entirely on their own responsibility. Nominally, they are elected annually by the governors, but no meeting of the latter has been held (until lately) for more than two years. For questioning the validity of such proceedings one of the physicians has been dismissed, and two others suspended from duty. A special meeting of governors was lately called, to consider these and other abuses, and some further revelations may shortly be expected.

A tempest is also raging at the Queen's Jubilee Hospital, which, although as yet within the first year of its existence, has just figured within the law courts. One of the surgeons is also surgeon to the Margaret Street Infirmary for Consumption. At this institution it transpired, some months ago, that some of the staff were homœopaths. The matter came before the committee, who, however, upheld the homœopaths, whereupon the rest of the staff resigned. Others, however, were found to fill their places, among them being the surgeon whose action is now in question. His colleagues at the Queen's Jubilee Hospital took umbrage at his associating himself with an institution where some of the staff were homœopaths, and on his refusing to resign his appointment at Margaret Street promptly induced the committee at the Queen's Jubilee Hospital to suspend him from duty at their institution. He (Mr. Millican) has taken the matter into the law courts, and is so far (pending an appeal) victorious, having obtained an injunction against the authorities of the Queen's Jubilee Hospital. The latter, when beaten, made a plaintive appeal to the judge, urging that if Mr. Millican proceeded to extremities it would lead to the closing of their hospital. If this be true, it can scarcely be in so flourishing a state as has been currently represented.

Dr. Arthur Farre, F.R.S., died recently at the ripe age of seventy-six. He was a distinguished obstetrician, and for many years Professor of Obstetric Medicine at King's College and Physician-Accoucheur to the hospital. His appointment as Physician-Accoucheur to the Princess of Wales (and to some other members of the royal family) brought him prominently forward, and for many years no medical name was better known in the upper circles of society. He was a brother of Dr. Frederic John Farre, who died about a year ago.

At one of the West End metropolitan hospitals one of the surgeons is reputed not to confine himself very strictly to surgical practice. Meeting one of the physicians one day, he said to him, jocosely, "Ah, you don't know what I have got in this bag." "Well," said the latter, somewhat to his discomfiture, "I shouldn't wonder if it's a stethoscope."

A medical man died recently in the provinces who was within a few months of attaining his hundredth year.

OUR PARIS LETTER.

(From our Own Correspondent.)

INTERESTING OBSERVATIONS ON THE SPEECH CENTRE—THE DIAGNOSIS OF CANCER OF THE STOMACH—DEATH OF M. DALLY.

Paris, January 6, 1888.

In a lecture delivered by Dr. Mathias Duval, Professor of Zoölogical Anthropology, on the brain, he referred to the discovery of Paul Broca, viz., that each convolution would appear to be a distinct organ, and in prosecuting his researches in this direction he had more than one opportunity of verifying that which appeared a mere hypothesis. While surgeon of the Bicêtre Asylum, a man who, for several years, had lost his memory for words, was admitted into the asylum, where he died. At the autopsy M. Broca discovered that a chronic softening had destroyed, on the left frontal lobe, the posterior half of the second and third frontal convolutions. He concluded from this circumstance that the faculty of articulated language may have its seat in that region; but before pronouncing on the significance of this discovery, he wished to await the confirmation of his induction. In a short time other cases presented themselves, which favored him in his researches. A patient who had become dumb was admitted into the asylum, and it was supposed that, the tongue being paralyzed, there was simply loss of the faculty of speech. In this case also, at the autopsy, the same convolutions as those of the first patient were found injured. In fine, the post-mortem examination of eleven persons, who had been accidentally deprived during their lives, some of the faculty of speech, others of the memory for words, or that for the letters of the alphabet, removed all doubt from the mind of the celebrated anthropologist that these faculties resided in the affected convolutions. On these premises, Professor Duval believes himself authorized to announce that "the mechanism of thought, and of its expression, appears to consist of a series of distinct cerebral organs, and that we might conceive the concatenation of their action." It may be here remarked that the above is simply the system of Gall revived, with observations more precise and more scientific.

In the reopening lecture of the winter session at the Paris School of Medicine, Dr. Dieulafoy, Professor of Medical Pathology, selected for his subject the diagnosis of cancer of the stomach. After having gone over the principal signs and symptoms of this affection, he compared it with other maladies with which it is liable to be confounded, and stated that at the same time these signs and symptoms, that is to say, those that are recognized as classical, are, after all, only probabilities. There is one sign, however, that Professor Dieulafoy dwelt upon as being a most important one, and almost pathognomonic of cancer of the stomach, and that is the absence of hydrochloric acid in the gastric juice. It is true that this sign has been known to the profession for some time, but as it has not been constantly found, doubts have been entertained as to its real value as a diagnostic sign in this malady. Professor Jaccoud, however, in the latest edition of his clinical lectures, states that, for the sign in question to have an absolute value, one must establish not the momentary absence of the hydrochloric acid, but the *persistence of the absence* of this acid in the gastric juice. Dr. Dieulafoy then gave the means for testing the presence of hydrochloric acid, which is as follows: A few drops of a concentrated watery solution of bright green, dropped into a test-tube containing distilled water, communicates a blue tint to the latter. If to the distilled water a few drops of the solution of bright green be poured into normal gastric juice previously filtered, which may be easily obtained by introducing into the stomach an india-rubber tube an hour or an hour and a half after a light repast, the gastric juice assumes a green tint. If the hydrochloric acid is in excess, the coloration obtained is the same as that observed on the mixture of bright green with distilled water; that is to say, that the gastric juice is tinted blue. In cancer of the stomach, the secretion of the hydrochloric acid is always diminished; it is even sometimes entirely absent. This fact has already been brought to notice by other observers, and Dr. Debove was one of the first to have made it known in France.

The lecturer stated that for his part he had twice to resort to this means of diagnosis, and twice he had obtained precise information. It concerns two women, one of whom had the classical signs of cancer of the stomach, the other the appearances of dilatation of that organ accompanied with cachexia. In both the patients the hydrochloric acid was absent, and the autopsy confirmed, for the two cases, the diagnosis of cancer. Dr. Dieulafoy therefore looks upon this sign as the only certain one we possess at the present time for diagnosing cancer of the stomach.

At the last meeting of the Academy of Medicine, M. Riche, a distinguished chemist, read a paper on some researches he had undertaken some time ago, to ascertain whether nickel was really toxic, as has been published by some authors; and, after several experiments on animals, he was led to conclude that nickel, in rational doses, is not toxic. Its action is comparable to that of iron, which it very much approaches in chemical composition, and M. Riche believes that nickel, employed as a therapeutic agent, would give results comparable to those we obtain from iron, antimony, and arsenic, as a stimulant of nutrition.

Dr. Dally, the well-known orthopedist, has just died at the age of fifty-four years, from diabetes, from which he had been suffering, more or less, for some years. He was also a distinguished anthropologist, and was professor of ethnology at the School of Anthropology. He was the author of several remarkable works, among which may be cited "The Present State of Medical Doctrines in their Relation to Philosophy and Science," "Remarks on Lunatics and Criminals as regards Moral and Legal Responsibility," "Researches on Consanguineous Marriages and on the Pure Races," "On the Order of Primates and Transformism," "The Place of Man in Nature," "The Hair as a Characteristic of the Human Races," "New Resources of Physiological Orthopedics."

INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In your issue of December 24th, Dr. George T. Stevens complains that I did not wait for the publication of the paper itself, instead of trusting to your report of the proceedings of the section of the International Congress before which it was read. My reasons for trusting to your report was simply that a long experience had convinced me of the great accuracy of The Record, which in this case was supported by the fact that the September number of the *American Journal of Ophthalmology* contained precisely the same statements. It seemed, therefore, to me, that the place in which the statements complained of had appeared was also the most proper place for any objections to them to be made. If The Record was wrong in its report, I feel quite sure that it will insist upon making any corrections suggested by Dr. Stevens which are in accordance with the facts of the case. But I do not see that Dr. Stevens himself intimates that The Record was wrong in what it said, but only suggests that I should have waited until the paper itself was published, and that, if I had done so, I "might have had reason to suspect that there are still important problems worthy of solution, respecting the so-called 'insufficiencies of the ocular muscles.'" In answer to this, I have only to say that it was not at all in regard to what was going to be published that I raised my objections, but as to what had already appeared.

As to "there being still important problems to be explained in regard to the so-called 'insufficiencies of the ocular muscles,'" and that these will be shown in the forthcoming paper, I would say that whenever Dr. Stevens writes anything which is really new and true in regard to insufficiency, I shall be the first to congratulate him; but I may be, perhaps, allowed to remark that it must be of a very different calibre from the statement that "there could not be an insufficiency of both interni and externi at the same time," or the assertion that where there was "diplopia, homonymous of 4° at twenty feet, and crossed of 5° at two feet, there seems to be a contradiction of results and a problem to explain." There is no contradiction of results, and no problem to explain, which has not been explained a quarter of a century, more or less, ago. One might as well claim originality, as, indeed, I heard it done the other day, for the determination of the amount gained by the tenotomy, by the use of a prism immediately after the operation, and the regulation of the effect by the employment of controlling sutures, which is also about a quarter of a century, more or less, old.

Again I say, that in the face of the numerous long and exhaustive articles of Von Graefe in regard to the insufficiency, paresis, and paralysis of the muscles of the globe, in face, too, of the writings and operations of Alfred Graefe, Giraud Teulon, Woinow, Knapp, Noyes, Derby, Theobald, and a host of others, I thought the statement that the literature of the subject was very scanty, and what existed would lead one to infer that only one of the muscles was liable to insufficiency, was neither correct nor just, and that it ought not to go unchallenged.

Dr. Stevens' statement that more operations are now performed for supposed insufficiency of the muscles of the eye than formerly is, I believe, perfectly correct. The same indications are present, and the same absolute necessity for their performance, under certain conditions, exist now as they did twenty years ago, when the writer divided both externi for asthenopia, in a case in which there was no strabismus ("Transactions of Amer. Ophth. Soc.," 1869, p. 35), and pointed out the fact that, in the treatment of squint and insufficiency, "hitherto too much attention had been paid to the condition of the interni and refraction, and not enough to that of the externi and accommodation." Others had done the operation abroad before this, and it has been repeatedly performed since by my confières and myself in this country. Von Graefe and Leber years ago divided the superior rectus for insufficiency of the inferior rectus, as others as well as myself have since done. This does not look as if other muscles than the interni "had been ignored or barely mentioned," as Dr. Stevens asserts. Had Dr. Stevens written his paper for the general profession, the matter might be somewhat different, but it was written for the edification of a set of experts who had been invited from all parts of the globe.

It would be very natural, through the diffusion of knowledge, the increase in the number of operators, and the immense increase in population, that the number of these operations should also largely increase. It has not, however, struck me that this is anywhere near as much the case in ophthalmic hospitals, as alleged by Dr. Stevens, as in private practice. Thus we see, by the last report of the Manhattan Eye and Ear Hospital, just issued, that out of 5,698 eye cases, "insufficiency" of the interni, let alone operating, occurred only six times, and that of the externi only once.

But even if these operations are performed more frequently than formerly, it does not prove that it is a measure to be so frequently employed. Still, it was more in regard to the physiological laws underlying "insufficiency" that I referred than to the application of the operation, which, in some quarters, seems to be limited only by the category of disease itself, multiplied by all the muscles of the globe, multiplied by the limit of tolerance as to the number of times each muscle can be operated upon. This is, of course, a matter of individual judgment, but to me, personally, the very frequency of the operation, as it is now performed, seems to be one of the saddest pages in American ophthalmology. I want to be candid in this matter, and I readily admit that it is the failures which I see and hear of, and not the successes. As, for example, cases in which the advancing glaucoma steadily advances in spite of the operation, in which the epileptic fits still continue or grow worse, in which progressive disease of the spine goes on progressing, in which the tumor of the orbit increases in growth, in which the headaches do not get well, in which the chronic diarrhœa is not checked, while the divergence of the eye produced by the operation is added to it. All this is to me, at least, very sad, and I hope to soon see that the day for indiscriminate operations upon the muscles of the eye, where no good can possibly follow, and where much harm is often done, has passed.

With these few remarks, I will follow Dr. Stevens' advice, and patiently wait until his paper is published. This I shall read with interest, as I shall the forthcoming report of the New York Neurological Society upon these matters.

Yours truly,

Edward Loring, M.D.

128 Madison Avenue.

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 8 to January 14, 1888.

Tesson, Louis S., Captain and Assistant Surgeon. Relieved from duty at Headquarters, Division of the Missouri, and as examiner of recruits at Chicago, Ill., and ordered for duty as post-surgeon at Watervliet Arsenal, New York, relieving Captain Henry G. Burton, Assistant Surgeon. S. O. 5, A. G. O., January 7, 1888.

Barnett, Richards, Captain and Assistant Surgeon. Ordered from further duty in Division of the Atlantic, to duty at Fort Riley, Kan.; to take effect at the expiration of his present sick-leave. S. O. 5, A. G. O., January 14, 1888.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 14, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	3
Scarlet fever	144	19
Cerebro-spinal meningitis	1	1
Measles	46	2
Diphtheria	177	50
Small-pox	6	0
Yellow fever	0	0
Cholera	0	0

Glossodynia.—Dr. Ueagitot says that this condition is met with almost always in neuropathic or asthmatic persons. It is very tenacious. The treatment should comprise bromide of potassium and hydrotherapy, and applications of cocaine or the galvano-cautery.

Dryness of the Throat from Excessive Tea-drinking.—Dr. Walker-Downie has made a number of observations on this subject, which he reports in the London *Practitioner*. Some years ago he pointed out a form of dry pharyngitis occurring in badly fed anæmic women, which he then in great part ascribed to the excessive use of cheap, and therefore inferior, tea. On inquiry it was found that those women had tea with almost every morsel of food of which they partook, and the tea, of a rank order, was not simply infused, but literally *stewed*. For a time, in addition to proscribing the use of tea (recommending the substitution of cocoa or milk), he advised the liberal use of farinaceous food with milk, and prescribed a chalybeate tonic, under which the patients rapidly recovered. After a time he prescribed no medicine, directing the change of diet indicated alone, with the same beneficial results. But patients are never thoroughly satisfied unless they get a bottle, and as preparations of iron materially assist in the cure of the accompanying anæmia, he has returned to his former prescription. Those patients when asked if they use much tea confess to it freely, but add that since the throat became so dry they have quite lost taste for it—have "turned against it." In all such cases he looks upon this form of dry pharyngitis, which does not involve the naso-pharynx as in *pharyngitis sicca*, as in great measure due to the gastric derangement—the dyspepsia—induced by the constant use of stewed tea shortly before, with, or immediately after meals, as well as to the local effect on the pharynx itself of this frequently applied astringent and irritant lotion. And just as we forbid the use of tobacco in certain inflammatory conditions of the mouth and fauces, so the total abstinence from tea should in all cases be rigorously enjoined.

Fatal Poisoning from Eating Toad-fish.—The following case is reported by Dr. Spofforth, of Sydney. The deceased was a Chinaman named Ah Wy, about forty-two years of age; he resided in a hut about fourteen miles from Manly, with another Chinaman, Ah Chin. On Saturday evening, January 15, 1887, they cooked about five fish which they had caught in the river, making a dish of soup. One of the fish was about four inches in length and nearly as broad, it was spotted on the back, it could be blown up like a bladder, and if struck would burst and make a noise like a pistol. Both men ate of the soup at 7 P.M., but Ah Chin partook only of a little of the gravy. At ten o'clock Ah Wy said that he was unwell and began to vomit; an hour afterward he asked his comrade to fetch some medicine. He went to a European's house and got some mustard and salt to form an emetic with; on his return to the hut at midnight he found Ah Wy unconscious, and at 2 A.M. on Sunday he died—seven hours after eating part of the toad fish. Ah Chin took some of the emetic. It seems that the reason for Ah Chin eating but little of the soup was that he did not consider that one of the fish used was wholesome, and he told this circumstance to his comrade; the latter, however, said he believed it to be very good. A *post-mortem* examination was made by myself, which showed that the stomach was about three-parts filled with partially digested fish, and the mucous membrane was inflamed, chiefly at its pyloric extremity. The intestines were healthy; the other organs of the body were considerably congested—otherwise healthy. The toad-fish belongs to the genus *Tetraodon*, which is poisonous. Some of the fish belonging to this order are very good eating. The coroner remarked that some years ago three children were poisoned by eating toad-fish, and died; and that part of their vomit was eaten by cats, and they also died.—*The Australian Medical Gazette.*

Subcutaneous Injections of Ammonia in Acute Alcoholism.—Inject under the skin a mixture of one part ammonia with two to six parts water. Two or three minutes after the injection an erysipelatous redness is observed around the puncture, and the next morning some soreness. Glinsky has seen a patient comatose from alcohol recover consciousness within three minutes after such an injection.

The Physiological Action of Chromium.—Dr. Pander, of Dorpat, publishes an account of some researches he has made on the physiological action of chromium. The compound which he found to answer best was the double lactate of chromium and sodium. Chromic acid and its salts produced both acute and chronic symptoms, salts of chromic oxide causing only chronic or, at most, subacute forms of poisoning. The chromic-acid compounds were found to be a hundred times more toxic than those of chromic oxide. The acute forms of poisoning show themselves by the disturbance of the respiration and of the central nervous system; chronic forms affect the skin and also the mucous membranes when air containing finely divided chromic oxide is allowed to come into contact with them. The heart's action was not directly affected by any of the preparations. The chief as well as the earliest morbid changes appeared in the kidneys under the form of parenchymatous nephritis, followed by the interstitial form; also in the gastro-intestinal tract, where inflammation, ecchymoses, and swollen follicles were found. There were also morbid appearances in the blood and the spleen. In chronic cases the spleen was shrunken and the hepatic parenchyma had a cloudy appearance. Chromium was found to be absorbed both when given hypodermically and also when administered by means of the gastro-intestinal tract, at least when soluble compounds were employed.

Chromic-acid preparations were absorbed with great rapidity, both by the skin and the stomach. When in very small quantities chromic acid and its salts were reduced to chromic oxide. The elimination of chromium took place mainly by the kidneys, but also to some extent by the liver and bowels. Death was caused in acute cases by arrest of respiration and disturbance of the central nervous system; in chronic cases by morbid changes in the blood, the kidneys, and the digestive tract. Dr. Pander was unable to find any indication as to the value of chromium as a therapeutic agent.—*The Lancet.*

A FUNGUS IN THE EAR.—Dr. Salelles describes a case of a rare vegetable parasite, *aspergillus flavescens*, obstructing the external meatus of the ear of a young man. After syringing away a quantity of black matter, a smooth glistening substance of a dirty white color with black spots was seen, which was the mycelium of the fungus studded with dark spores. All attempts to remove this with forceps provoked so much pain that they had to be given up. Glycerine was dropped into the ear, and in two days' time the patient returned in terrible suffering, the dark spores having been developed and forming a large mass. After this had been removed by syringing, alcohol and tannin were introduced, and at the next visit the mycelium was removed by the syringe, the membrana tympani becoming visible. In a month's time the fungus began to reappear, but was rapidly subdued by similar treatment, which was followed up by the daily instillation of dilute spirit for a short time. No further return occurred, and the patient entirely regained his power of hearing. The introduction of the fungus appeared to have been due to the use of some oil of sweet almonds, which had been kept for some time in an open bottle, and which the patient had been in the habit of dropping into his ear along with milk, as he suffered from otalgia.—*The Lancet.*

HOUSE POISON.—If the condensed breath collected on the cool window-panes of a room where a number of persons have been assembled, be burned, a smell as of singed hair will show the presence of organic matter; and, if the condensed breath be allowed to remain on the windows for a few days, it will be found, on examination by microscope, that it is alive with animalculæ. The inhalation of air containing such putrescent matter causes untold complaints which might be avoided by a circulation of fresh air.—*Philadelphia Bulletin.*

VERY OLD AGE.—The death is reported from Constantinople of a man named Dimitrios Antippa at the extraordinary age of one hundred and fifteen years. The deceased was born at Cephalonia in 1772, and, though in his later years he settled down as a merchant in the Turkish capital, he had passed his earlier days in Paris during the Reign of Terror, having had among his personal friends Marat, Danton, and Robespierre. To the last M. Antippa retained his clearness of intellect.

SALICYLATE OF MERCURY is recommended as an antiseptic powder for external application in the treatment of wounds, syphilitic sores, etc. It is a white amorphous powder, free from odor, tasteless, and neutral to test-paper. It is slightly soluble in water and alcohol. It contains 0.2 per cent. of water of crystallization, and fifty-nine per cent. of mercury.

A JAPANESE GIANTESS.—According to native journals, Japan can boast of a phenomenal giantess. Though only twelve years and five months of age, she is said to stand eight feet high and to weigh over two hundred and seventy pounds; her hands measure over nine inches in length, and her feet fifteen inches.

CHILDREN'S WINTER DRESS.—There is a tolerably general impression in many quarters that in order to promote the health of children it is advisable to subject them to a "hardening" process. The meaning of this term it is needless to explain further than to say that its aim is to encourage native energy by opposition, to engender strength of mind and body by early participation in the struggle for existence. The principle is in itself a wholesome one, and is not without its parallel in the history of nature's processes. Care is most necessary, however, in its application. Without such care it may be, and frequently has been, overdone. In particular must it be remembered that all success in the adoption of this plan in education depends on the possession by a child thus trained of a basis of sturdy physical vigor. A delicate child, if treated after the same method, would languish and probably succumb. We have been led into this train of observation by noting the frequency with which one finds children of both sexes and of different ages, constitutions, and positions in life treated after one uniform prescription of hardy training. We would now concern ourselves particularly with that aspect of the question which has to do with clothing during such inclement weather as prevails at present. That considerable variation of opinion should obtain among parents with regard to this subject is only to be expected. Here, it may be said with truth, is room for the wise exercise of private judgment, and here we may in many cases find occasion to apply the maxims of the hardening system. So much may safely be granted, but we must not forget that certain essentials cannot be dispensed with under any plan adopted. Among these the maintenance of bodily heat and dryness is all-important, and certain of the most prevalent customs of domestic life incline us to believe that the fact is but slightly understood. The hat, for example, is often, in the case of girls, far too light and too cool. Instead of straw, we would substitute some form of woollen material, just as boys, with few exceptions, are commonly provided with hats of wool or felt, which are at once light, comfortable, and suitably protective against weather. Underclothing is another matter which does not as yet receive adequate attention. We still find the linen shirt or chemise worn very commonly next the skin. This is an error in personal hygiene which cannot under any system be excused. Summer and winter, indeed, present no material difference as regards the choice of an undergarment. Lighter or heavier, the material certainly should vary in accordance with the degree of external cold; but throughout the year no other substance is so wholesome or so preventive of chill as a woollen fabric. Of the feet we need, perhaps, hardly speak. For them, as for the rest of the body, a casing of wool is the prime requisite; and, indeed, the use of this material as a general investment for the skin will be allowed by members of the profession generally to be the great regulating principle in arranging the dress of children, whatever the view most approved in their physical education.—*The Lancet.*

CONTRIBUTION TO THE PHYSIOLOGY OF RENAL SECRETION.—Some time ago Hermann stated that the secretion of the kidneys varied on each side. It was objected to his experiments that reflex influences consecutive to exposure of the ureters might explain the difference. Zuelzer has studied the question in a case of vesical ectopia. Iodide of potassium, given by the mouth, appeared in the urine from one ureter at a different time from that of the other side; salicylic acid showed the same difference. Chemical analysis also proved that the proportions of urea, phosphoric acid, and sulphuric acid differed on the two sides. Great differences were observed in the quantity and density of the urine discharged from the two sides respectively. This difference leads Zuelzer to think that the composition of the blood in the aorta is far from being uniform.—*The Lancet.*

CARLSBAD NOTES.—A correspondent of the *British Medical Journal*, writing about this popular resort, says, among other things: Can anyone say what is the precise physiological effect of swallowing a couple of tumblers of hot saline water early in the morning on the liver?—or on the stomach?—or on the kidneys? Can anyone distinguish between that effect—whatever it may be—when a similar solution is swallowed in like quantity at home or at Carlsbad? Can anyone say what is the physiological difference of effect between swallowing the same quantity of hot water only—or of drinking it hot or cold? These are elementary questions, and go to the bottom of any rational use of these waters, or of any scientific basis for prescribing them. Of course, I am not speaking of that dark and obscure puzzle which everyone thinks he can clarify for himself, and which he fondly calls his "clinical experience;" but to speak only of the demonstrable physiological action of the waters. I think I am not going too far when I say that, notwithstanding the scientific attainments of the Carlsbad physicians, not one of them has yet attempted to establish the physiological effects of these waters on healthy bodies as a preliminary to determining their uses in pathological conditions. We are yet in a very unscientific stage in ordinary therapeutics, but the therapeutics of "baths and wells" appear to be left, designedly, or undesignedly, as in a state of black darkness, which leaves their whole application and mode of operation in as purely hypothetical a state as in the darker ages of medical ignorance. Is it not surprising that a whole body of educated men should be willing to go on prescribing so many half-pints or pints of hot saline water without knowing what is the action on the healthy body, of one, two, or three pints of such fluid; that thirty thousand people should be every year put through the *régime* without anyone knowing the relative value of its component parts; that each spring should solemnly be inscribed with its temperature in centigrade and Fahrenheit, and that minute analyses should be paraded of the infinitesimal differences of springs, all flowing from one geological stratum, without an attempt to discriminate the physiological value of such differences? Not all patients pay the traditional respect to medical prescription which is characteristic of Carlsbad, and there is naturally a good deal of good-humored banter about the rigidity with which quantities, times, and sources of water-drinking are regulated. A little caricature which is shown in some of the shop-windows shows a grave and spectacled physician bending over a sprightly dame whose pulse he is feeling. She complains that she has not slept well last night. "Ah, then, madam," he says, "you must drink a glass less water to-morrow morning." "But, doctor," she says, "the day before yesterday, I took a glass more and I slept excellently well." "Then," he replies, "you may take an extra glass to-morrow morning." "Oh, then," she retorts, "it seems that it comes to the same thing whether you take a glass more or a glass less." "Yes, madam," is the answer; "but, only when you take it under medical advice." There is a good deal of sound philosophy in the candid answer. It is not always acted upon. A Russian gentleman, of whom I heard this year, considered that as he was paying his "*Cur Tax*," and the glasses of the water were ordered for him, he could hardly have too much of a good thing, and he put himself on a daily regimen of sixteen glasses, and he was surprised that it did not agree with him. But then he was a Russian, and he had the traditional example of Peter the Great, who visited Carlsbad in 1711, and of whom it is related that he was told to take three glasses of the waters before breakfast, but either his German or the local physician's Russian being bad, he thought three large jugfuls were meant. He succeeded in swallowing one jugful, and was choking over the second, when the physician appeared and apprised him of his error. However, he was wont to do things heroically, and his daily quantum is recorded as twenty-three glasses, which he took usually at one sitting. He wrote to his wife, the Empress Catharine: "I am well, thank God, and so we all are, only our bellies are swelled out with water, for we drink like horses, and have no other occupation." He concludes by stating that a Carlsbad cure is a very complex therapeutic agent. It is a rest cure, a diet cure, an air cure, a music cure, an exercise cure, a mind cure, and a body cure. Its efficiency is made up of a great many elements, which have by time, experience, liberal expenditure, and enlightened management, been brought together in aid of the natural treasures and territorial advantages of the place.

SULPHUR WATERS IN LARYNGEAL PHTHISIS.—Dr. Charazac, writing in the *Revue Médicale de Toulouse* for September 1, 1887, calls attention to the injurious effects of the use of sulphur waters in cases of tuberculosis of the larynx. The sulphides, he says, excite a congestion of the laryngeal mucous membrane, and if their use be persisted in, what was a nearly dormant tuberculosis of the larynx may pass into an acute miliary tuberculosis. Bergeon's method, therefore, whatever may be said for or against its value in pulmonary phthisis, would seem to be contraindicated when the larynx is involved in the morbid process.

TETANUS.—According to MM. Nocard and Brieger, tetanus is a disease transmitted to men and animals by the agency of a pathogenic organism which infects wounds or other suitable soils on the surface of the body. The organism does not penetrate far beyond the limits of its point of inoculation, but exercises its deleterious influence by means of certain products of an alkaloidal nature, and of which there are, according to Brieger, four kinds—tetanin, tetano-toxine, spasmo-toxine, and another not named. The alkaloids have a special affinity for certain parts of the motor nervous system, causing excessive discharges of nervous energy, on which the muscular spasms are directly dependent. M. Nocard found that dried blood and pus scraped from instruments which had been used to geld horses (all of which died of tetanus), when inoculated beneath the skin of rabbits and guinea-pigs, caused tetanus; and yet infusions made from the medulla oblongata and spinal cord of animals dead from tetanus were not capable of causing tetanus in other animals into whom some of the infusion was injected. The argument is not free from fallacy, but the conclusion drawn is that the spinal cord and medulla are acted upon by a strychnine-like substance, of course incapable of cultivation, but derived from the multiplication and growth of organisms elsewhere existing.—*Lancet.*

QUEBRACHO IN SURGICAL PRACTICE.—Dr. Bordeaux, of Brussels, who has used quebracho a good deal during the last year or two, speaks very highly of it as a topical application for wounds and burns. The liquid extract is the preparation employed, and it is painted with a brush over the wound like collodion. The slight pain it causes is very transient; it becomes hard in an hour's time, forming a brownish crust, which can only be loosened with the aid of hot water. This crust is quite sufficient protection, no dressing being required. It promotes healing by first intention, and greatly assists the process of granulation.—*Lancet.*

EFFECTS OF PHOSPHORUS ON YOUNG ANIMALS.—Dr. Alexander Kisel, of St. Petersburg, who has made a series of observations on the effect of small doses of phosphorus on young animals, has found that it never exerts any beneficial effect on the growth of bone, but that, on the other hand, the apparently slight disorder of the digestive functions which very small doses produce is liable to result in death. When given to puppies in doses of 0.0001 gramme per kilogramme of weight, symptoms of chronic poisoning were produced, with atrophy and disintegration of the bones. In doses of half this amount the development of the animal was retarded, but those equal to 0.000033 gramme per kilogramme of weight appeared to be innocuous and produced no effect at all upon the body.—*Lancet.*

The Medical Record

ON THE CONDITIONS CONDUCIVE TO THE *EARLIEST POSSIBLE* HEALING OF OPERATION WOUNDS.[1]

BY W. W. KEEN, M.D.,

PROFESSOR OF SURGERY IN THE WOMAN'S MEDICAL COLLEGE OF PENNSYLVANIA, SURGEON TO ST. MARY'S HOSPITAL, ETC.

I CAN hardly hope to say much to-night that will be new to this distinguished audience of practical surgeons. But it is sometimes well to review the results of progress in various directions, to reiterate old truths, and to add, here and there, a little both in the way of practical hints and of emphasized aphorisms.

The conditions conducive to the *earliest possible* healing of operation wounds I would state as follows:

1. The use of the antiseptic method before and during the operation and at the later dressings.
2. Thorough drainage.
3. Complete approximation both of the edges and raw surfaces.
4. The use of antiseptic dressings.
5. Securing absolute rest during the period of repair.

First: The use of the antiseptic method before and during the operation and at the later dressings.—Of this I need say but little. The surgeons who do not use the method, though they may vary the means employed, are few in number and, as a rule, of little prominence. Boiling water and strict cleanliness belong as much to the antiseptic method as do corrosive sublimate and carbolic acid. My own practice in the cases I shall briefly relate has been to employ the sublimate and carbolic acid in the usual way. I may say, in passing, that I very rarely employ iodoform, partly on account of its detestable and persistent odor, and partly on account of its poor germicidal properties. That my results justify its non-use I think will be admitted.

The spray is now generally conceded to be superfluous, as a rule. We have slowly but surely learned the lesson that our instruments and sponges, our finger-nails, our dressings, and the skin of the patient are far more apt to be the sources of infection than the air; and that what does obtain access through the air can be neutralized by constant flushing of the wound with hot water or some germicide.

I desire, however, to lay some stress on the need of more thorough cleansing and disinfection of the site of the operation during the twenty-four hours before operating, especially in localities in which dirt may accumulate, as in the umbilicus and in regions covered with hair. Horsley's careful preparation of the scalp, before operating on the brain, marks, in my opinion, a distinct advance, and should be a model for our practice in other regions of the body. To shave off the hair, wash the skin with a nail-brush and soap and water, then with turpentine and ether, and then apply a wet sublimate dressing for twelve to twenty-four hours before operating, gives but little trouble; and, I have no doubt, will still further reduce the mortality, already so delightfully low.

Of course, the same antiseptic method employed at the operation should be employed at every redressing until the wound is healed.

Secondly: Thorough drainage.—As a rule, considerable blood and serum accumulate in a wound during the first twenty-four hours, while the later discharge is only bloody serum and is small in amount. Hence two separate objects are to be attained—first, to secure the escape of the more abundant, thicker, and coagulable wound-fluids of the first twenty-four hours; and, secondly, to secure the escape of the less abundant, thinner, and practically non-coagulable later fluids. In a paper read before the Philadelphia Academy of Surgery, December 1, 1884, under the caption "Combined Tubular and Capillary Drainage of Large Wounds," I stated my own practice for some years and its advantages. Rubber or other fenestrated tubes, of greater or less calibre, suffice admirably for carrying off the secretion of the first twenty-four hours; but if retained much longer these tubes not only act as setons and foreign bodies but, as granulations arise, the eyes become blocked up, and thus frustrate the very purpose for which the tubes are employed; and, if long retained in place, when removed the tubes often leave sinuses which, if long, are almost certain not to heal from the centre toward each end, but to close at two or three intermediate points, and so pen up the slight discharge and produce retention and suppuration. Decalcified bone drains have so often been disappointing, either by not being absorbed or by collapsing from too early softening, or by occasionally becoming sources of infection, that they have not answered, I think, our earlier expectations. On the whole, rubber or glass drains answer the purpose best. But they must not be left long in place.

For the later moderate serous oozing, capillary drains answer best. The material may be horsehair, catgut, or rubber threads. The capillarity of a bundle of these materials is their chief advantage—an advantage, however, that is lost if the fluids to be drained are at all thick. Considerable personal experience, extending now over about ten years, leads me quite confidently to commend again the following method of combined tubular and capillary drainage. Before the wound is closed a fenestrated rubber tube, of suitable size, is placed in the wound, and alongside of it is laid a mesh of from five to ten strands of catgut or fifteen to thirty strands of horsehair. At the first dressing, at the end of twenty-four hours, the rubber tubing is carefully removed, and the horsehair left *in situ*. At the second dressing, on the fifth day, all the horsehair may be removed, or two or three strands left in place, to be removed at the next dressing, according to circumstances. The early removal of the tubing allows the surfaces to fall together, and so prevents the formation of any tubular sinus; and if the healing process is rapid, as is generally the case, fine granulations easily penetrate between the threads of the horsehair, which thus offer little obstruction to the union of the surfaces, and yet will conduct off any slight amount of wound-fluids.

The method of removal of the horsehair is important as a minor detail, but not a little conducive to the speediest healing of the wound. If removed in mass, the mesh of horsehair may tear apart, to some extent, the slightly united surfaces. Accordingly, after separating the matted thread at both ends of the mesh of hair, I always remove them singly, and with great gentleness. This avoids all pain, and, what is more important, does not in the least disturb any slender means of union between the surfaces of the wound. Two or three hairs may be left for two or three days longer, to drain the slight temporary sinus left by the removal of the rest of the mesh, but usually this is a needless precaution.

---

[1] Read at a meeting of the Surgical Section of the New York Academy of Medicine, held January 9, 1888.

The horsehair could be introduced, of course, when the tubing is removed, instead of placing it in the wound primarily, but this causes much pain, and, worse, it does mechanical violence to a wound already in the early stages of repair—a matter always to be deprecated to the utmost. So careful am I as to this detail that, after separating the matted hairs, I usually cut off the projecting threads at one end (excepting the few I intend to leave in place), so that their stiffness and the blood coagulated on the projecting ends shall do no violence to the interior of the wound while being withdrawn.

I have spoken chiefly of horsehair. If this be used, it should always be carefully washed with soap and water, then in turpentine, and, after thorough disinfection by a sublimate solution, should be kept in carbolized water till used. Care must also be taken that all short hairs are eliminated from the mesh.

The more absorbable forms of catgut I do not like, since they swell, soften early, and, being coarser than horsehair, their capillarity is less. The finer, chromic catgut, however, does not swell, is durable, and answers tolerably well. But even fine catgut is often harsh and stiff, and therefore, mechanically, much less well suited to attain our object than horsehair. With rubber threads I have no experience, but I should judge that they would not answer so well as either of the others.

Of course, the drains may be multiple if the wound requires it.

The point of exit of the drains is important. It should, of course, always be in such a position as to favor the escape of the wound-fluids by gravity, and both tubing and horsehair may often be carried, with the greatest advantage, through a button-hole at the lowest angle of the wound, as in breast cases.

The drainage of cerebral and abdominal operations is so special as to be rather beyond the province of this general paper, but I may be permitted, perhaps, to call particular attention to the advantages, in abdominal operations, of a disinfected cotton rope when inserted within the calibre of glass drainage-tubes. The cotton forms, practically, a series of capillary tubes, and so favors drainage, even against gravity (as in the abdomen), and is a distinct advance, I believe, in surgical technique. I purpose trying both cotton and horsehair and catgut, placed within the rubber tubing, in ordinary operative wounds, to see whether they may not add to the usefulness of the tubes. Possibly, also, instead of placing the mesh of horsehair or catgut alongside of the rubber tubing for the later capillary drainage, it may prove to be the better procedure to place them in the tube, and after twenty-four hours to remove the tube, leaving the horsehair or catgut *in situ*. My only fear is that they might possibly block up the tube. Experience will have to decide the question.

I feel, also, that I would be derelict were I not to allude, in this presence especially, to the efficient influence of Professor Markoe in impressing on the profession at large the importance of thorough drainage.

Thirdly: Complete approximation both of the edges and raw surfaces of wounds.—First, as to the edges: Skin should be brought in exact contact with skin, edge to edge, continuously from one end of the wound to the other. Not seldom the stitches are made so tight as to cause some overlapping. The overlapped raw surface, not being able to unite with the skin beneath, must cicatrize, and this often delays the definite cure by several days; or the opposite error is committed, of placing the sutures so far apart as to allow of several gaps, each one of which must heal by the slow process of cicatrization, instead of direct union, and so produce a similar delay of several days in the definite cure. In the days when every silk suture was, for the time, a seton, such parsimony in the number of sutures was pardonable; but now that we have the wire, and, better, the antiseptic catgut suture, it is not only allowable, but it is a duty, to put the sutures so close together that not a single point shall gap, even in a minute degree. The small, slit-like wounds of the Hagedorn needles, also, heal more quickly than those made by other needles, and, as another minor detail, are to be commended.

Secondly, as to the raw surfaces: They may be approximated either by pressure or by sutures. While pressure is, theoretically, the best method, it is often difficult of attainment in practice for mechanical reasons. When possible it should be employed; but if not, then we may employ "sutures of relaxation," so secured at one end that we can readjust their tension according to the needs of each case.

"Étage sutures," or rows of buried catgut sutures at different levels, are employed by Martin, with great advantage, in the perineum, and they have been employed for some time in closing the abdominal wall after laparotomy. I have used them with great advantage in these cases, and I venture to suggest their use in the closure of such other wounds as are mechanically suited to this procedure. I have not yet so used them in amputations, etc., but I shall certainly test their merits on the first occasion. One of the most striking uses of catgut is the possibility of using it freely in situations where it can be thus buried, and, having performed its function in the occlusion of vessels or the uniting of deep surfaces, be absorbed and never heard of again. Here, again, we may mark a step in advance—one of the many minor details all tending to perfection in results.

By such complete approximation of raw surfaces we secure a triple object—the prevention of hemorrhagic oozing, the prevention of the accumulation of any later wound-fluids (and so lessen the need for drainage, which is, at best, a necessity to be avoided wherever possible), and, finally, the promotion of immediate union of the wound-surfaces at every point.

Fourthly: The use of antiseptic dressings.—Of such dressings I shall say nothing in detail, since they are so uniformly used by all good surgeons abreast of the times. I shall only call attention to one point, in which, I think, the profession is following an incorrect practice, if we wish to secure the earliest possible healing of wounds.

The tendency of to-day and for some time past has been to retain the first dressing upon the wound until the healing process is completed, or nearly so. This I think an error. I show you here a number of primary dressings, removed by myself at the expiration of twenty-four hours, and a number of second dressings from the same cases, removed on the fifth day. Contrast them. See the amount of blood in the first dressings, rendering them harsh and stiff, alike uncomfortable to the patient and unsuited to the wound, if we desire the most favorable conditions for speedy healing. Such a saturated dressing may not be only a discomfort; without great care the fluids may become sources of putrefaction. Certainly, if this hard, harsh, and stiffened first dressing be removed after a day, and the wound lie at rest covered with a soft, smooth, flexible, and nearly dry gauze, the chances of its healing rapidly are greatly increased. In practice I have found it so, and the cases to be related, I think, will prove the assertion.

Moreover, with the method of combined tubular and capillary drainage I have proposed, it is needful to redress the wound after twenty-four hours in order to remove the drainage-tube. Not only do I redress on the first day after the operation, but I redress again, usually, on the fifth day; sometimes, in small wounds, as early as the third or fourth, and occasionally as late as the sixth, day. One reason for the redressing on the fifth day is that by this time there is no further need for capillary drainage, except, possibly, by two or three strands of horsehair; and the other threads should then be removed, lest they, too, begin to act as setons. A second reason is, that by this time the sutures often begin to cause irritation, and to cut through the tissues, even if wire or catgut be employed, especially if there have been any tension on them. Sometimes small stitch-abscesses form, which may even cause a considerable rise of temperature and delay the final cure by several days. If another reason be required, ample justification will be found in the fact that with the method outlined above and the last point directly to be mentioned, in the majority of cases, the wound will be by that time entirely healed.

It is properly called a very speedy cure when any good-sized operation wound is well in ten days to two weeks, but I have so often been able to secure this same result in *five days* that I can confidently urge a trial of the method in all its simple but important details, assured that the verdict will be most favorable. The earliest possible healing of wounds all will admit to be our highest aim. It abridges the pain; it shortens the period of apprehension both to patient and friends—and how welcome the announcement that the cure is not almost, but altogether complete; and it lessens materially the expense—an item we should never forget, even with the well-to-do, and still more in the case of those who must pinch and sacrifice in order to meet unexpected demands upon a slender purse.

In fact, when a patient now asks me how long a stay in town, or how long a cessation from business, will be required, if it be an ordinary tumor, or amputation, or similar operation, and I can get ample flaps to secure primary union, it is my custom to assign ten to fourteen days as a maximum limit. I rarely exceed the greater and most frequently secure the shorter limit, sometimes still less. This, of course, is modified by bad general health, or severe local inflammation, involvement of bones, and other such causes of delay.

Fifthly: Securing absolute rest during the period of repair.—In general this is always recognized, but many of its lesser details are overlooked. After an amputation of the breast, a careful surgeon, having secured the dressings by a chest-bandage, will always, of course, enforce absolute rest of the arm by securing it to the body by a bandage or, as I prefer, by a strip of flannel. This I secure by two rows of large safety-pins to the chest-bandage; one row placed behind the arm and the other in front of it, so as both to support the upper arm in the recumbent posture and prevent its motion, while the forearm may be held up by a sling. In any but small wounds of the extremities, and also of the neck, suitable splints should always be applied, to enforce the dictum of absolute rest. These statements may possibly seem almost superfluous to older surgeons; but I have so often seen them neglected by younger surgeons, and sometimes even by those of some experience, that I may be pardoned for alluding to them by way of re-enforcement.

Again, rest is not only to be had in this, as it were, gross way, but by the greatest gentleness in the redressings. Hence, in the removal of a dressing, there should be no rude tearing of it off, but great care should be used in softening it by hot water at adherent points, seeing that it does not adhere to the drains and thus roughly displace them. All sponging or syringing should be done efficiently but gently, and in the removal of the tubing and, later, of the horsehair it should be done slowly and carefully, the latter thread by thread. By the "scientific use of the imagination" we should look below the skin, see the tender granulation-tissue uniting the wound-surfaces, the delicate capillaries ready to be torn by the slightest sliding of one raw surface upon the other, or by even gentle tension on the horsehair drain. Such care in the first and second redressings "pays well" in the securing of the speediest possible union.

I have insisted much on minute attention to trivial details. Taken singly each one is trivial, but taken together they mean much, and their result is simply delightful, alike to the patient in speedy cure, and to the surgeon in scientific results which a few years ago were impossible, even to the best of us, but are now every-day occurrences.

One other suggestion I venture to make. Immunity from return after the removal of malignant growths, I believe, is greatly favored by such speedy healing without irritation and inflammation. If so, every single day's abridgment of the process of repair becomes a matter of vital importance that should on no account be neglected.

To illustrate and enforce the practice I have thus described, I will relate in brief a few cases, which speak for themselves, and which may prove, I hope, a justification of much that is trite in what I have said.

CASE I. *Sarcoma of right breast.*—Mrs. S——, aged eighty-three; short, stout woman, weight one hundred and eighty pounds, with very flabby breasts. Tumor size of double fist; incision sixteen inches long; skin had to be loosened and united by *glissement.* Dressed on first day after operation, when the tubing was removed. Dressed on the fifth day; horsehair and stiches removed; entire wound healed. Highest temperature, 99°. Slight gaping at one point of great tension followed removal of the sutures, but it healed in three or four days. This is the oldest case I ever operated on. She is now entirely well, one year after the operation. It would have been wiser had I left the sutures in place at the point of tension for two days longer.

CASE II. *Scirrhus of left breast.*—Mrs. S——, aged seventy-five. Dressed on first day after operation and tubing removed. Second dressing on fifth day, when horsehair and all stitches were removed; wound entirely healed. Highest temperature, 99.8°. On the eighth day she came down-stairs herself, from the third story, and admitted me. Fifteen months after the operation, is still entirely well.

CASE III. *Scirrhus of both breasts.*—Mrs. B——, aged forty-one. Right breast removed first. Dressed on first and fifth days, when respectively the tubing and horsehair and stitches were removed; wound entirely healed. Was out of bed on fourth day, and out for a walk on the tenth day. On the twelfth day the left breast was removed, and with similar treatment was well on the fifth day. Three weeks after the first operation, and nine days after the second, she dressed her own back hair (involving, of course, much tension of the pectoral regions, but without any pain) and then travelled home, over three hundred miles, writing me that on her arrival she felt better than when she started. Highest temperature, 100°. Eleven months after the operation, is still well.

CASE IV. *Scirrhus of left breast.*—Mrs. K——, aged fifty. Similarly treated; was well in five days; all stitches and drainage out. Highest temperature, 99.5°. Nine months have passed and she is still well.

CASE V. *Scirrhus of right breast.*—Mrs. A——, aged fifty nine. Similarly treated, and well in five days; stitches and drainage all out. Highest temperature, 100.2°. A year after the operation, is entirely well.

CASE VI. *Scirrhus of left breast.*—Miss. B——, aged thirty. Similarly treated, and entirely well in five days. Highest temperature, 99°. Nine months after the operation, is entirely well.

CASE VII. *Adenoma of left breast, steadily growing.*—Miss R——, aged nineteen. Similarly treated; well in seven days. No rise of temperature.

CASE VIII. *Atrophic scirrhus of right breast.*—Mrs. M——, aged sixty. Similarly dressed; entirely well in seven days. Was sitting up, out of bed, on the day after the operation, when I arrived to dress the wound; never missed a night's sleep or a meal, except on the day of the operation. No rise of temperature. Three years later a small tumor appeared in the cicatrix, which was removed, with a similarly happy result. Over five years have been passed in perfect health since then.

CASE IX. *Lymphadenoid sarcoma of left arm.*—Mr. R——, aged thirty five. Tumor as large as an English walnut just above the internal condyle of the humerus. Similarly treated, and well in seven days. Tumor returned in four months. A second operation for its removal, similarly treated, was followed by recovery in seven days. Tumor returned in two months. Amputation of the upper arm just above the middle. Similarly dressed; entirely healed in five days. Was out of bed smoking a cigar on the fourth day, and on the seventh resumed his duties at the Electrical Exhibition. No rise of temperature. Three years and four months have passed, and he is in perfect health.

CASE X. *Goitre.*—Miss H——, aged thirty-seven. Almost complete thyroidectomy; moderate hemorrhage. Tumor reached below the top of the sternum and outward to the two carotid sheaths. Highest temperature, 99.4°. Similarly dressed; all well in five days. Three days later a small collection of serum at the centre of the wound was discharged by a small opening which healed in a week. Two years and four months have elapsed without any return, and with no influence on the general health other than a beneficial one.

CASE XI. *Arterio-venous aneurism of right arm* (for details, see the *Medical News*, December 24, 1887).—Miss L——, aged eighteen. Similarly dressed after a tedious dissection, lasting one and a half hour, with many ligatures; all well in eight days. Highest temperature, 100.5°.

CASE XII. *Enlarged scrofulous glands of neck.*—Miss S——, aged twenty-two. Removed eighteen glands, by incision, reaching from the mastoid process to the clavicle. Sterno-cleido-mastoid dissected loose its entire length; operation lasted over an hour. Dressed on the first day and tubing removed. On the third day I redressed the wound, as her temperature had risen to 102°, but found everything in good condition. Again on the fifth day, when I found the wound entirely well; horsehair and stitches removed. By this time it was evident that an attack of acute articular rheumatism had set in. It ran a prolonged and severe course, but had not the least deleterious influence on the healing of the wound.

CHLOROSIS AND HEART DISEASE.—Excessive anæmia being present, and the heart not being hypertrophied, the diagnosis of the cause of heart-murmurs is frequently very difficult. M. Duclos has returned to this battlefield of clinicians, and sums up his conclusions in the following propositions: In true chlorosis, no matter the number and site of the cardiac murmurs, the basic murmur is never absent, and is most often systolic. In true chlorosis the carotid murmurs, varied and more or less marked, are always present. In genuine chlorosis the bruits are generally more intense and more extensive than in heart disease, and are markedly out of proportion to the circulatory disturbance; further, the cardiopulmonary circulation remains free, and any disturbance in it indicates the persistence of a valvular lesion, and generally of the mitral valve. We do not join issue with M. Duclos in the general tone of his arguments, which are sound enough so far as they go; but the most frequent clinical difficulty is not so much the differential diagnosis of severe chlorosis from heart disease as it is the distinction or discovery of valvular lesion in the presence of less marked anæmia.—*The Lancet*, November 5, 1887.

RACE AND THE COLOR OF THE HAIR AND EYES.—M. P. Topinard is engaged in collecting statistics concerning the color of eyes and hair in France. Over two thousand persons have consented to lend their assistance in this undertaking. Among these are naval and military surgeons, directors of workhouses and factories, doctors, chemists, etc. M. Topinard has already received over eighty-seven thousand observations from different persons. The undertaking promises to be very successful, and next year we may look for a complete map, or census, in which the different shades of hair and eyes of the French population will be indicated by arrondissements.

THE VALUE OF LIMPING AS AN AID TO DIAGNOSIS.[1]

BY THOMAS L. STEDMAN, M.D.,

LATE ATTENDING SURGEON TO THE NEW YORK ORTHOPÆDIC DISPENSARY.

THE object which I have in presenting this paper for your consideration this evening is to direct your attention to the very valuable aid which we may derive, in the clinical study of certain diseases, especially when occurring in children, from the phenomenon known as limping, or claudication. It would of course be impossible, in a communication of this nature, to study in detail all the possible affections in which limping may be an occasional or constant symptom, and a mere enumeration of them would only bore you. I propose, therefore, to consider briefly the different varieties of claudication, referring to some of the more important only of the diseases which present a limp as one of their symptoms.

Many physicians, I fear, are wont to regard a limp, in a child at least, as a matter of trifling importance; especially is this the case when the limp is intermittent. It is looked upon as the expression of fatigue, or as a habit, and is dismissed as a matter of little moment. It is, however, a symptom often of the greatest importance, and frequently, indeed, is the only sign indicative of very serious lesions, the further progress of which might have been arrested by timely treatment, had not the significance of the early limp been overlooked and its warning disregarded.

In normal locomotion there are certain oscillations of the body, which vary much in character and degree in different individuals, but which are always in three directions—vertical, lateral, and antero-posterior. Just as no two persons look exactly alike, so no two walk alike, and we must avoid the error of confounding peculiarities in gait with limping. The best definition of a limp is, I think, that given by Le Dentu, in Jaccoud's "Dictionnaire de Médecine." He characterizes it as an inequality in the oscillations of the body during progression, the characteristic phenomena of the type observed being repeated at each step. As the oscillations of normal progression are in three directions—antero-posterior, lateral, and vertical—so also are the irregularities of a limp; but they may be more pronounced in one direction than in another, and this is a point often of considerable importance, as I hope to demonstrate to you later. In studying a limp it is important to note, not only the particular category to which it may belong, as regards the predominating direction of its oscillations, but also the time of its occurrence—that is to say, whether it takes place at the begining of a step or during the act. In the latter case the normal mechanism of locomotion is at fault, while in the former a mechanical cause for the limp will be found in the inequality in the length of the limbs. The rhythm of locomotion is likewise to be studied. The oscillations may be apparently normal as to degree, but the step taken with one member is seen to be of much shorter duration than that made with the other limb. This occurs frequently in painful affections, when the patient favors one limb more than the other. The constancy of the limp is also to be taken into consideration. In commencing hip disease, for example, the limp is commonly intermittent, being absent for longer or shorter periods, and returning again without apparent cause, or in consequence of some slight traumatism. Again, when there is obstruction to the blood-supply of a limb, a limp is not present at first, but becomes evident only after the patient has been exercising for a short time. Finally, the time of day at which a limp is present should be considered. In some cases claudication is noticed only in the morning, or after a period of prolonged rest, and disappears after the patient has exercised for a time; or, again, it may become noticeable only toward evening, after the patient has been on his feet all day.

---

[1] A paper read before the Manhattan Medical and Surgical Society, January 7, 1888.

A limp may be caused by an inequality in the length of the two lower extremities, or by some lesion of the skin, muscles, nerves, arteries, bones, or joints of the affected limb. We will glance briefly at some of these more common causes of limping, in order the better to comprehend the clinical significance of this important symptom.

The limp due to inequality in length of the lower extremities is the simplest form of claudication, and is easily recognized, as is also its cause, which is usually self-evident. A shortened leg may, however, be compensated for, in part or wholly, by extension of the foot, and in the case of a woman, whose dress conceals the deformity, even a considerable shortening may pass unperceived by any but the most careful observer.

Lesions of the integument may occasion the limp of pain, as is seen in the case of irritable ulcers of the leg, or of corns or other painful cutaneous affections of the feet. Extensive cicatrices near a joint may give rise to a condition similar to anchylosis, and the resulting limp will be that characteristic of this impairment of articular function.

Contractures of the muscles are a not uncommon cause of claudication, the particular variety of which will depend upon the deformity produced. The characters of the limp, varying according to the joint whose motion is restricted, will be described when we come to the lameness from articular troubles. It should not be forgotten that there may be pain accompanying the muscular contractures, and in such cases active joint disease might erroneously be diagnosed.

Paralysis may cause limping in any of several ways. In the early stages, before alterations in the form and nutrition of the limb have taken place, there is the limp due to impaired function. When the flexors of the thigh are affected, the limb must be thrown forward by a rotating motion of the body around the sound side; when the muscles on the anterior surface of the thigh are involved, extension of the leg is accomplished by a sort of flail movement; in paralysis of the flexors of the foot the toes droop and the limb is practically lengthened, so that the patient is obliged either to raise himself on the sound side while bringing the affected limb forward, or to throw the latter outward and swing it around to the desired position; when the calf-muscles are the ones paralyzed, the normal extension of the foot cannot take place, and there is an inequality in the vertical oscillations during progression. After the disease has existed for a time there is more or less atrophy, and, in children, arrested growth, with its consequent shortening; usually, also, muscular contractures occur, and lead to impairment of joint-function. The most usual forms of paralysis met with in children are infantile paralysis and infantile hemiplegia. The so-called spastic paralyses and the ataxic gait of tabes dorsalis need only be referred to, since they do not cause a true limp, although they modify normal locomotion very materially.

A painful limp may be due to sciatica or other forms of neuralgia. In hysterical joint-affections the limp is similar to that caused by the true disease there simulated.

There is a peculiar form of limping, which has been well described by Charcot, Terrillon, and other French observers, which is due to obstruction in the main arterial supply of the limb. The limp is one due to pain, and is intermittent in character. The patient, on getting up in the morning, or after a prolonged rest at other times, walks well, with no suspicion of a limp; but after going about on his feet for a time, usually only a few minutes, or at most an hour, according to the amount of exercise taken, he begins to experience sharp pain in the affected member, which finds expression in a decided limp. If the walking is persisted in, this pain soon becomes so severe as to render further locomotion impossible, and the patient is forced to rest. After a time of absolute quiet he attempts to walk again, and finds that the pain and the limp have entirely disappeared; but a little more exercise brings them back again in full severity. This peculiar form of claudication has been found to be due to interference with the vascular supply of the limb, which eventually may result in gangrene and loss of the member.

Affections of the bones may cause a limp in one of several ways. In the early stages of osteitis, or periosteitis, stepping on the diseased limb causes pain; the patient favors the leg as much as he can, and endeavors to throw the weight of the body as quickly as possible over to the sound side. The rhythm of locomotion is in such case markedly altered, and there is a manifest inequality of the lateral oscillations. Here the claudication occurs during the step. In some cases of necrosis there is lengthening of the bone, due to irritation and consequent abnormal growth at the epiphyseal end. When too early union of the epiphyses has occurred from any cause, the growth in the bone is retarded and shortening results. A similar condition of shortening may follow disease of the articular end of the bone, operations, fractures with longitudinal displacement of the opposing fragments, and tumors causing a retardation of growth or loss of substance of the bone. There is here a difference in length of the two members; the limp occurs at the beginning of the step, and is marked by exaggerated vertical oscillations, without necessarily any noticeable disturbance of rhythm. This is one of the least deforming varieties of claudication, and the difference in length of the two members may, if it be not too great, be almost perfectly compensated for by extension of the foot upon the shorter side, or by the wearing of a high-soled shoe.

Lesions of the joints are among the most common causes of lameness. Here the limp may be caused by pain, by restriction to normal articular motion, or by weakness of the joint unaccompanied by either pain or restricted movements. When due to pain resulting from injury or disease, the limp is of the same character as that symptomatic of inflammatory bone-lesions, but is often more marked in proportion as the joint-sensitiveness is greater. In commencing joint disease, or in hyperæmia of the articular structures before any actual inflammation is present, there is often a limp or a "favoring" of the member, which is unaccompanied by pain, and is due to reflex influences or to nature's effort to protect the joint. The limp in this case is similar in character to that caused by painful affections, but is wholly involuntary, and the patient himself is often unable to explain why he walks lame. When the articular motion is restricted, the limp will vary in character according to the joint affected and to the variety of deformity present. In anchylosis of the hip in extension, the limp is characterized by a peculiar balancing of the body in an antero-posterior direction. As the weight rests on the sound side the anchylosed limb is thrown forward and the body backward, and then, as the weight is transferred to the anchylosed limb, the body goes on in advance while the leg on this side remains behind. Sometimes the limp consists in a sort of rotation, now to one side and now to the other, as the axis of rotation is transferred from one limb to the other. The body is turned half around on the sound limb, and then the motion is reversed by rotation on the heel of the anchylosed side. This may occur when but one hip is anchylosed, but is the only possible mode of progression without crutches when there is anchylosis in extension at both hip-joints. When one hip is stiffened in flexion, the vertical position of the body is maintained by compensatory lordosis of the lumbar spine, but the limb is shortened by reason of its position, and there is an exaggeration of the vertical and also of the lateral oscillations. When the spine is also rigid the body cannot be held erect, and there is an inclination forward. In such cases oscillations in each of the three directions occur during locomotion.

In sacro-iliac disease the patient tries to avoid, as far as possible, resting the weight of the body on the affected side. He drags the foot along, moves it slowly and only to a slight extent, and places it flat on the ground, avoiding the heel-and-toe movement. He usually leans slightly forward in walking, and in standing inclines the body over toward the sound side. Sometimes the toes are directed slightly outward.

When the knee is stiffened in extension the normal shortening produced by flexion cannot take place; the limp occurs during the step, and is characterized by increased vertical oscillations, as the patient must extend the foot more on the sound side, so as to raise the body and allow of room for the carrying forward of the stiff leg. If the joint is held in the position of flexion the limb is shortened, and claudication occurs at the beginning of the step.

In anchylosis of the ankle with extended foot (talipes equinus) the limb is elongated, and the characteristic limp of inequality in length takes place. When it is stiffened in flexion (talipes calcaneus) the limp occurs during the step, and is occasioned by absence of the normal lengthening which should take place from extension of the foot in walking. In talipes varus, in addition to the limp due to unequal length, there is usually a lateral oscillation from unsteadiness of support. In talipes valgus, besides the limp caused by imperfect extension of the foot, there is commonly also an altered rhythm in the steps, depending upon the pain felt in walking.

When joint disease is active and pain is present, as well as restriction to motion from reflex muscular spasm, there is a mixed limp, due to the elongation or shortening of the limb from position, and to the pain caused by intra-articular pressure and attempted motion. The rhythm is altered, and lateral and vertical, and sometimes also antero-posterior, oscillations are produced.

In congenital dislocation of the hip the limp is peculiar. It occurs at the beginning of the step, and is prolonged during its progress. The sinking of the body seems to continue as long as the weight rests upon the affected limb, and at the same time there is a very marked lateral deviation. In bilateral dislocation the gait is waddling and extremely awkward, but there is usually no limp, strictly speaking, since the oscillations on the two sides, though abnormal, are equal.

In cases of relaxed and weakened joints, resulting from previous inflammation, with effusion and distention of the articular structures, or from any other cause, the gait is uncertain. There is not always a true limp, but there is apt to be a more or less marked lateral or vertical oscillation, not necessarily occurring at every step, but taking place irregularly whenever the articulation gives way.

Claudication is of very common occurrence in Pott's disease of the spine. If the psoas muscle is contracted, the thigh becomes flexed and a limp is caused. Limping may also be excited by the peripheral pains of spinal caries, or there may be paraplegia, more or less complete, with consequent interference with normal locomotion.

In lateral curvature of the spine there is not uncommonly an obliquity of the pelvis, with apparent shortening of one lower extremity, and frequently there is actual shortening, occurring either as a consequence or as a cause of the scoliosis. In this case, of course, a more or less noticeable limp is present.

In conclusion, I hope you will pardon me for calling your attention once more to the great importance of this symptom of limping. It is often the first sign of a serious trouble, which may possibly be averted if discovered in time, but which will work great and lasting injury if the warning given by the limp is neglected and the disease allowed to progress untreated. This is especially true in the case of hip disease in children. A limp is almost always the first intimation which the commencing articular trouble gives of its presence; but, as the claudication is often intermittent, the parents, and even at times the physician, are wont to disregard it, or to think it is only a "bad habit," and it is not until pain and deformity supervene that the true cause of the limp is recognized. No limp, however trivial, occurring in a child, should ever be lightly passed over. The little patient should be carefully examined, and all his joints tested; and even if no disease be discovered at the time, he should be watched, so that if any trouble does exist it may be recognized in its incipiency and receive appropriate treatment.

102 East Fifty-seventh Street.

THE USE OF THE CURETTE FOR THE RELIEF OF HEMORRHAGE DUE TO UTERINE FIBROIDS.[1]

By HENRY C. COE, M.D.,
NEW YORK.

Curetting the uterine cavity is such a familiar operation that it is unnecessary to refer to the ordinary indications and technique. It is my purpose in this brief paper not to suggest any new application of this useful little instrument, but simply to invite discussion of a simple method of treating a formidable condition, which, though familiar to gynecologists, does not appear to have met with the recognition which it deserves among the profession in general. Profuse hemorrhage from the non-puerperal uterus is an alarming phenomenon to the practising physician. It is noticeable that men who preserve the utmost *sang-froid* in the presence of post-partum flooding are sometimes completely at a loss in cases of menorrhagia, and, instead of searching for the root of the evil and striking at it directly, they will temporize, and rely upon medicinal treatment, hoping that the patient may by good fortune be enabled to tide over the period that elapses before the menopause, in deference to the popular idea that at this time the hemorrhage will suddenly and mysteriously cease. But this hope is more or less illusive, for not only may the presence of the fibroid prolong the climacteric period, but the tumor may actually increase in size, while the loss of blood becomes more, instead of less, profuse. In short, the patient may become gradually weaker and weaker while the attendant is waiting for nature's cure, until, when he is finally aroused to a real sense of her serious condition, and decides that a radical operation is necessary, she is no longer in a condition to submit to it. Every gynecologist is familiar with mournful examples of what "might have been" in such cases if the cause of the menorrhagia had been discovered earlier and an intelligent effort made to remove it.

There is a general opinion among practitioners that there is no middle ground in the treatment of these cases between internal medication (perhaps combined with intra-uterine applications, astringent douches, and tamponing) and a radical operation. Modern text-books are responsible for this. "The number of articles devoted to the consideration of operative measures for the cure of this affection," says Winckel, "is five times as great as that of those advocating medical treatment, and in the latter ergot and electrolysis are alone mentioned with any degree of confidence." The same conservative writer is almost the only one who alludes to the use of the curette, in these words: "But when all these remedies are no longer of avail the uterus must be sounded, or eventually dilated, in order to see whether an adenoma of the mucous membrane is present, and, if so, to remove it. It is advisable to curette the uterus in any case, and after swabbing it out with absorbent cotton wrapped upon the tip of a sound, to check the hemorrhage, if present, with solution of the sesquichloride of iron."

---

[1] Read before the Obstetrical Section of the Academy of Medicine, November 23, 1887.

It is important, before proceeding to the practical part of this subject, to call attention to a few elementary facts in uterine pathology, at the risk of repeating what is already well known to my hearers. It would seem unnecessary to insist upon the fallacy of the idea that in hemorrhage from fibroid uteri the blood comes from the tumor itself, or that, except in rare cases, it is due to the rupture of blood-vessels either within the tumor or in the mucous membrane covering it. Yet we read in a recent edition of a well-known text-book on gynecology that "the loss of blood takes place from the rupture of some little vessel on the lining membrane of the canal covering the portion of the partially projecting tumor." Of course, if this explanation were correct, the treatment advocated in this paper is based on entirely erroneous principles; but it is impossible to accept this theory, even from a strictly clinical stand-point. Without dwelling on points which are sufficiently familiar, let me remind you that the hemorrhage from fibroid uteri is frequently quite out of proportion to the size of the tumor, and also to the depth of the uterine cavity as indicated by the probe. Thus, a large subperitoneal tumor, filling the abdomen, may give rise to pressure-symptoms alone, while an insignificant submucous polypus occasions exhausting menorrhagia. The difference does not lie in the relative vascularity of the growths, nor does their position alone furnish an explanation. Again, we know that the hemorrhage is apt to be most excessive from uteri which contain intramural growths that project into the uterine cavity, *i.e.*, are partly submucous. But such growths are even less vascular than the two former varieties. Now, the hemorrhage is essentially a menorrhagia, like that due to endometritis fungosa, and hence is directly referable to menstrual congestion. In neither case is it usual for a gush of blood to occur without any warning, as would be the case if it came from a ruptured vessel, but the hemorrhage begins like the normal menstrual flow, and subsequently becomes excessive. The natural inference is, that in the case of fibroid uteri also the blood comes directly from the hypertrophied mucous membrane. Lay open the uterine cavity in a typical specimen of intramural fibroid; it may be only moderately enlarged, but even on gross inspection it will be evident that the endometrium is thicker and more spongy than it is in a normal uterus, while here and there are to be seen those translucent cauliflower growths with which we are so familiar under the name "fungosities." Sections made through the uterine wall at different points will show clearly the hypertrophy of the mucosa, and accompanying it an immense increase in its usual vascular supply. Each fungosity represents a relatively enormous bleeding surface, as is daily proved clinically, as well as anatomically. Now, this hypertrophy of the endometrium is noticeable everywhere except at one point, and that is over the surface of the projecting tumor, where it is actually atrophied, in consequence of long-continued pressure, and, so far from containing large vessels which, according to the theory to which reference was made, rupture under the increased pressure of the menstrual nisus and are thus the direct source of hemorrhage, it is less vascular than normal, containing only a few dilated veins. Even in the case of polypoid growths, the bleeding is seldom from the tumor itself, unless there be complete obstruction to its venous circulation or actual ulceration. In consequence of this localized atrophy of the mucous membrane covering the tumor, according to Gusserow, there is produced collateral hyperæmia in the rest of the mucosa, leading to swelling and hypertrophy of the same, and which at the time of the menstrual congestion gives rise to profuse hemorrhage. "That, moreover [to quote from the same writer], the changes in the uterine mucosa are not always due to such purely mechanical causes as hyperæmia, from local stasis, but that inflammatory swelling of the endometrium may occur, in consequence of the irritation produced by the tumor, is proved by those occasional cases of hemorrhage, accompanying pure subperitoneal fibroids, in which we find here and there in the uterus changes that may be best described as chronic metritis, and that they are more frequent in connection with interstitial growths."

The pathological sequence is now clear. The presence of a fibroid tumor (especially of the submucous or combined submucous and intramural variety) determines an increased afflux of blood to the uterus, not so much because of the extra amount of blood required for the nutrition of the growth as by reason of the venous obstruction induced by its presence. The entire uterus hypertrophies in consequence, but this hypernutrition affects principally the endometrium, which undergoes the change so common in subinvolution, but much more marked. When to this general hyperplastic endometritis is added the collateral hyperæmia induced by localized atrophy of the mucosa covering the tumor, the true cause of the hemorrhage is presented beyond a shadow of doubt. The blood is derived from the entire mucous surface, and not from any single ruptured vessel or sinus. This explains why a tumor of insignificant size may give rise to a hemorrhage as alarming as it is apparently inexplicable, while a growth twenty times as large may cause only a slight increase in the normal menstrual flow. The difference is to be sought for, not in the difference in vascularity between the growths, nor entirely in their location, but in the condition of the endometrium in the two cases. Why the latter is much hypertrophied in one case and only slightly so in another, where the conditions are apparently similar, we cannot positively determine, any more than we can tell why the removal of the mucosa arrests the hemorrhage in one instance and not in another. We may be sure of the source of the hemorrhage, while we cannot control the ultima causa.

These simple anatomical facts, which are easily demonstrated at the operating-table and in the dead-house, are capable of a direct practical application. Can we not, by removing one of the principal links in the pathological chain, relieve the alarming symptom under consideration, even though the active cause remain? In short, if the hypertrophied mucosa is scraped away, will not the hemorrhage be lessened? I do not desire to make any sweeping assertions, based on insufficient and imperfect statistics, regarding the benefit obtained by the use of the curette in cases of hemorrhage from fibroid uteri, but I am sure that there are few gynecologists who cannot recall instances in which curetting, adopted merely as an empirical measure, has been followed by unexpected, not to say brilliant, results. It is unfortunate that no reliable tables of statistics have been compiled; those derived from hospital-records are not conclusive, since, although there is no lack of cases (at least in the Woman's Hospital) in which hemorrhage was relieved by a single operation, the after-history of the patient is seldom obtainable. Of course, the hemorrhage tends to recur, just as the lining of the uterine cavity is renewed after being thoroughly removed. Curetting is not to be regarded as other than a temporary relief under any circumstances. That it may afford relief for a long period is shown by the following typical case:

An unmarried woman, aged twenty-five, was under my care about five years ago, suffering from menorrhagia, which had reduced her to a decidedly anæmic state. She also had moderate pressure-symptoms. Examination revealed the presence of an interstitial fibroid as large as a man's head, which caused uniform enlargement of the uterus, the cavity of the organ having a depth of between four and five inches. Medication, tamponing, and injections were of slight avail, and the patient's condition was considered sufficiently serious to warrant a radical operation. As an experiment, the uterine cavity was thoroughly curetted, a quantity of hypertrophied mucous membrane, or fungosities, being removed, after which an application of tincture of iodine was made, and the same was repeated three or four times subsequently. At her next period a marked diminution in the flow was noted, and soon after she passed from under my observation. Previous to this she asked me if it would be wise for her to marry, to which I returned a decided negative, setting forth to her not only the dangers to which she would be exposed if she became pregnant, but the immediate risk of a return of the hemorrhage which might be entailed by the marriage relation. She wrote to me twice—once after an interval of three or four months, to say that her monthly flow was nearly normal in amount, and again, after a longer interval, saying triumphantly that she had been married for several months and felt better than ever before. The last news from her came in the shape of a letter from her physician, in which he stated that she had become pregnant, had aborted, and was flowing so profusely that her recovery was doubtful.

The subsequent history of the case does not concern us. The point to be emphasized is the prompt relief afforded by the use of the curette, which relief would doubtless have been long-continued, had not the patient deliberately incurred the danger against which she was warned. The excessive loss of blood which followed the early abortion was due not alone to the inability of the uterus to contract properly in consequence of the presence of the fibroid, but also to the fact that under the double influence of the tumor and pregnancy the endometrium became more hypertrophied than it was originally.

Theoretically, the objection may be raised that the simple removal of the mucosa is not a scientific method of dealing with the pathological condition as a whole. This is true ; still, it must be remembered that we are discussing the treatment of a single objective symptom—hemorrhage. Subjective symptoms, due to the mechanical pressure of the tumor on adjacent organs, ducts, or vessels, are not considered in this paper ; these alone may be so serious as to justify hysterectomy. Intrauterine growths should, of course, be removed at once ; simply scraping off the mucous membrane would be unsurgical when the polypus itself could be extirpated without serious risk. The condition in which we may hope for success from curetting is, as has been pointed out, that of an intramural growth, projecting into the uterine cavity, precisely such a sort as surgeons are sometimes tempted to attack with the spoon-saw, and occasionally with unfortunate result. The technique of curetting is quite familiar, but it is important to remember that the anatomical conditions are different from those in an ordinary case of endometritis fungosa accompanying subinvolution. In fibroid uteri the os is frequently drawn up behind the symphysis, so that it is only with the greatest difficulty that an instrument can be introduced into it ; indeed, this is often impossible. Again, the uterine cavity may be greatly elongated, but narrow and tortuous, so that a curette could never be manipulated within it. But, in my experience, the endometrium is more often atrophied than hypertrophied, under the latter circumstances, so that curetting would do no good. Clinically, it is, of course, impossible to determine whether a given case presents exactly such anatomical conditions as will justify us in predicting a favorable result from the operation, but I would expect decided benefit where the tumor was of moderate size and the uterine cavity was considerably enlarged—where the hemorrhage was out of proportion to the size of the growth, and the sound revealed a general soft, spongy condition of the endometrium. For the rest, the operation should be performed about midway between the monthly periods, the patient being thoroughly anæsthetized ; the curette should be used vigorously, and as long as any shreds of hypertrophied tissue can be removed. The caution to apply iodine to the abraded surface at intervals after the operation is especially applicable here. It seems illogical to rest content with astringent applications alone, when the desired result can be obtained by scraping away the diseased tissue, and then retarding its renewal by subsequently applying the same remedies. I do not doubt that some of the good results obtained by Apostoli in treating uterine fibroids by passing powerful currents through the intra-uterine electrode are directly due to the charring of the mucous membrane with which the latter comes in contact.

Another important point is not to give up curetting until it has received a fair trial. Suppose the lining membrane does re-form in a few months, it can easily be scraped off again, and if the patient can be kept in this way from exhausting hemorrhages until the menopause, we have reason to feel better satisfied than if we had removed her ovaries and tubes, perhaps without attaining the desired result, not to speak of the more serious operations, enucleation and supravaginal amputation. The dull-wire curette is not the exclusive property of gynecologists. No special skill is required in using it. In spite of all that has been said and written in its favor, it does not seem to be as popular among the general profession as it should be, else uterine hemorrhage would not be such a bugbear as it is. It is conceivable that much good might be accomplished if the fact could be emphasized that it is not necessary to remove the entire uterus because of hemorrhage which cannot be controlled by medication. I can recall several fatal cases of hysterectomy, performed for the relief of hemorrhage from fibroid uteri, in which an examination of the specimens showed that the source of the bleeding was clearly the *interior*, not the *exterior*, of the organs.

It may be urged in objection that the operation recommended in this paper is uncertain in its results, and that the indications are not sufficiently clear ; the same applies to removal of the tubes and ovaries, and the relative risks are widely different. Curetting involves little more danger than does an intra-uterine application, and, being such an innocent procedure, we can afford to practise it simply as an experiment. No patient will object to it, even when presented in that light, if she understands that it may enable her to avoid a more serious operation. It is hardly necessary to add that we are not justified in allowing a patient to bleed to death while we are testing the value of the palliative measure.

In conclusion, I would again express my regret that the practical deductions made in this paper do not rest upon a more solid statistical basis. Definite facts are much needed, and these can only be furnished as the result of a series of observations made in private practice and extending over a sufficiently lengthy period to make evident the remote as well as the immediate effects of the treatment described. Such statistics need not emanate from specialists alone. This is a fruitful theme for collective investigation. The following is a brief summary of the points which deserve study :

1. The hemorrhage in cases of fibroid tumor of the uterus has its source, not in the tumor itself, but in the hypertrophied endometrium.

2. The hemorrhage is not directly proportionate to the size of the tumor, but to the extent of the mucous surface. Venous obstruction and the menstrual congestion in the mucosa are the chief active causes.

3. In certain cases the hemorrhage can be diminished for a considerable period by thoroughly scraping away the hypertrophied endometrium and repeating the operation as often as may be necessary to keep the menorrhagia under control.

4. Curetting is merely a palliative measure, but it may enable the patient to survive until she is relieved at the menopause, whereas radical operations too often result fatally.

5. Curetting in these cases should be regarded as an experiment, which, however, is so harmless and so frequently successful, that we are justified in giving it a fair trial before advising oöphorectomy, myomotomy, or supravaginal amputation.

6. The use of the curette requires no special skill. It

is an operation for the general practitioner, and is much more rational than to allow the patient to become exhausted by repeated hemorrhages which medication and other palliative measures are powerless to control.

THE INDUCTION OF PREMATURE LABOR IN AMAUROSIS AND AMBLYOPIA, IN CONNECTION WITH THE ALBUMINURIA OF PREGNANCY.[1]

By THOMAS R. POOLEY, M.D.,
NEW YORK.

Among the indications for the induction of abortion or premature labor in the albuminuria of pregnancy, disturbances of the vision have not received the attention which the great importance of the subject seems to demand.

It has long been known that pregnant women are liable to affections of vision, from slight impairment of sight to even complete and permanent blindness. This was known, too, before Bright's careful description of kidney affections and the discovery of the ophthalmoscope, and attributed to affections of the brain. It may occur at any time during pregnancy, or after labor, and may recur in several successive pregnancies; it is, however, more apt to occur in the later months. Blindness may last for weeks, and then, after labor, complete recovery ensue, or the sight may be permanently lost.

The changes occurring in the eyes, in the albuminuria of pregnancy, are essentially the same as those observed in the course of chronic nephritis. Without entering into a description of these, which is not necessary for present purposes, it will be sufficient to distinguish two ways in which the sight may be affected:

1. A sudden more or less transitory and complete loss of sight, uræmic amaurosis, without appreciable changes in the fundus oculi.

2. A gradual failure at first, not complete loss of sight, with characteristic changes in the retina and optic nerve, which in time may lead to blindness, neuro-retinitis Brightii, or albuminurica. These changes are so marked and uniform that the diagnosis of the kidney disease can be made from them alone.

These facts being so well established, it would seem strange that, until quite recently, no one had proposed the induction of premature labor solely with the view of arresting the progress of the eye disease; but such is the fact. The writer has looked over several of the more recent works on obstetrics,[2] with reference to this point, and while they mention the occurrence of visual disturbance, there is no suggestion as to this being an indication for bringing on premature delivery. We are naturally led from the foregoing facts to the consideration whether it is ever justifiable or proper to provoke premature labor for the restoration or preservation of sight alone, even when the other symptoms usually recognized as sufficient cause for this procedure may be wanting, which it is the main object of this paper to discuss.

For this reason, it seems especially desirable to consider the question before a body like this, composed of obstetricians and general physicians, rather than in a society made up of specialists alone. For the question as to the propriety of such a course, as well as the indications for its adoption, will be best settled upon a proper scientific basis by the obstetrician and oculist acting in conjunction. It will require the examination of the fundus oculi by a competent ophthalmoscopist, to decide whether the retinal mischief alone is sufficient to resort to such a serious operation, but there may be other considerations to be taken into account upon which he is not so competent to decide.

The credit of first having induced premature labor for the only reason that permanent blindness was threatened belongs to our distinguished Fellow, Dr. E. G. Loring, of this city, in an admirable paper on the subject of which we are speaking, which was published in the "Transactions of the American Ophthalmological Society" for 1883, and also reprinted in pamphlet form. Although Dr. Loring's case was not one of either uræmic amaurosis or retinitis albuminurica, in the sense in which we are now considering the subject, but of atrophy of the optic nerves, aggravated, if not caused, by rapidly succeeding pregnancies, it nevertheless deserves our consideration here as being the first case of the kind published where the operation was done for the preservation of vision.

The patient, in whom one eye was already blind, was thirty-five years of age. The vision of the other was threatened. She had had three children, and, before the birth of each, impairment of vision, so that after the third child's birth she was blind in the left eye, and in the right V. = $\frac{1}{3}$. Becoming pregnant again, and loss of the use of the remaining eye being feared, abortion was induced at the third month, and she made a good recovery, the vision becoming very much improved. Whether or not the condition of the kidneys had anything to do with the loss of vision in this case, it seems evident enough that the successive pregnancies had. The usual symptoms of albuminuria were wanting, and there were at no time evidences of albumen in the urine. But, for all this, may not the condition have been due to the effects of uræmic poisoning on the optic nerves, finally resulting in atrophy of the disks? In order to obtain the author's own opinion, a note was addressed to him, which is so interesting that we may be excused for quoting it: "I did not consider that my case depended upon kidney disease, as we are able now to recognize it. I went out of my way to insist that, after every known test had been exhausted, no sign of kidney disease could be found. Now as to whether, in this case, there was neuritis or atrophy depends, I think, on how we look at it. The ophthalmoscope certainly showed that there was some blanching of the disk—indeed, a great deal—but, on the other hand, would you say it was a case of *progressive atrophy* [a term which we had used in the letter to the doctor], which improved in vision from counting fingers in a few feet up to V. = $\frac{2}{5}$. There would seem to be, in these cases a mixture of inflammation (neuritis) and atrophy. If taken early enough, the inflammation may be reduced so that vision improves, and yet some atrophy remains, as seen by the mirror. You may speak of uræmic amaurosis, and, if so, what and where is the lesion? For example, there are cases of so-called uræmic blindness when there are no ophthalmoscopic signs at all, although in these there might have been, if death had not intervened. In a great many of them I am induced to think that there is a retro-bulbar neuritis as the initial lesion, which may show itself at a later day as an atrophy of the disk. Still, we know very little about the matter." Reference has been made already by the writer to uræmic amaurosis, but no attempt made to explain what the lesion in such cases is, as it is a mere matter of speculation, no change in the eye having been seen in such attacks. But, whatever may be the cause, there seems to be no good reason why atrophy of the nerve may not result from obscure disease of the kidney. Dr. Loring's suggestive remarks gain force when we consider that there are many cases of granular kidney in which albumen in the urine is not detected; at least, not for a long time. Aside from this very interesting case, which is briefly sketched, as the first of the kind, so far as ascertained, published, the author's paper includes the subject of disturbances of vision in the albuminuria of pregnancy, and very ably advocates the importance and propriety of the induction of premature labor in cases where loss of vision is threatened.

Since this publication would seem to justify the priority of Loring in recommending this important procedure, his case is given the first place in these remarks, and throughout this paper frequent reference to it will be made. There can be no doubt that his publication has created increased interest in the matter, as shown by another on the same subject, which soon followed, by Dr. W. O. Moore,[1] of this city, which is also a very interesting and instructive article. He shows that, although Loring's was the first published case in which premature labor was actually performed, Dr. W. J. Scott, of Cleveland, O., in 1875 called attention to the necessity of producing premature labor, but does not mention any case in which it was done. In a case reported by Dr. Holmes, of Chicago, premature labor was advised, not on account of the blindness but for the general condition of the patient, she having at the time pericardial effusion. Still more recently, the subject was quite fully discussed in a meeting of the New York Ophthalmological Society, April 11, 1887.

We shall now very briefly relate a series of cases, first, in which the patient was either allowed to go to full term, or where premature birth occurred spontaneously; and, second, where premature labor was induced artificially, to see whether the permanent results as to vision were improved by the procedure. By this means we can best judge of the advisability of this method of treatment.

Mrs. B——, aged thirty-six, seen by the writer, October 2, 1880, two weeks after confinement, in consultation with Dr. Lees, of this city. During pregnancy she had several attacks of dimness of vision, nausea, and headache, with albumen in the urine. Toward the latter end of the eighth month sight became more seriously affected, and continued after her confinement as a "film before the eyes." Examination of the eyes at this time showed a very well-marked, although not high, grade of neuroretinitis. There was venous hyperæmia, slight haziness of the retina, and the outlines of the nerve were indistinct; at the region of the macula lutea, several white patches, which assumed the stellate arrangement so characteristic of Bright's retinitis; albumen still in the urine, but much less than before and just after the confinement. The sight at this time was not accurately ascertained, as the patient was still in bed.

October 19th.—V. = $\frac{20}{40}$ in the left, and $\frac{20}{50}$ in the right. The ophthalmoscopic appearances had much improved, and there was still less albumen in the urine.

December 16th.—The ophthalmoscope showed a slight haziness of the retina and some dilatation of the veins; no longer any albumen. From this time on the patient made a good recovery, and the vision became normal. For a long time, however, she complained of asthenopia and blurring of objects. This lady has been under observation, occasionally, every year since this occurrence, now seven years ago; she has, fortunately, never again become pregnant, and has been in full possession of useful vision. This is one of the most fortunate recoveries which have come under our notice, and for this reason alone is here inserted. The result is hardly ever as good as this, for the later changes in the neuritis usually cause some atrophy of the nerve and retina, with corresponding loss of sight. In order to be impartial in the selection of cases, it has been reported as one in which premature labor was not induced. It will be noticed, however, that the permanent dimness of vision did not come on until the end of, or after, pregnancy. The temporary obscurations of sight were doubtless due to uræmic amaurosis, without changes in the retina or optic nerve taking place.

The following case is reported by Mr. Robert Lee, of London,[2] the particulars being furnished to him by Mr. Bowman, and is referred to in Loring's paper. On December 7th, Mr. Bowman was consulted by a lady who was pregnant, and "who had rather suddenly lost her sight in a great measure." The urine was found to be excessively loaded with albumen. At Mr. Bowman's suggestion the patient consulted Mr. Paget and Dr. West, who anticipated, Mr. Bowman says, as he did himself, "that the confinement would be attended with convulsions of a dangerous character." No ophthalmoscopic examination was reported. On January 9th, or about one month later, she had a premature confinement of a male fœtus, which was still-born. The patient regained her health and strength, but Mr. Bowman regrets to say that the sight has only partially returned. Eastlake,[1] quoted by Moore (*loc. cit.*) reports a case of a patient, aged thirty-four, who had had nine children at full term and no miscarriages. At the birth of the first child she had no ocular symptoms. On the second day after the birth of the second child, and after all her seven subsequent labors, she suddenly became totally blind in both eyes, which lasted from three to five weeks. An ophthalmoscopic examination of the eyes, long afterward, demonstrated only the existence of contracted retinal arteries and blanched optic nerves. No account of the examination of the urine was given, but the picture may have been that of the last stages of albuminuric retinitis.

Dr. Holmes, of Chicago,[2] publishes a case of which, although incomplete, inasmuch as he does not tell us whether artificial delivery, which was recommended by the attending physicians—not, however, on account of the blindness but the general condition of the patient—was actually performed, we nevertheless make use. A patient, aged thirty-five, primipara, whom he was called to see in consultation, in the sixth month of pregnacy. The retinæ were pale and œdematous, the disk indistinct, the retina scarcely visible, and the patient was totally blind in each eye, but there were none of the white exudations at the macula, or elsewhere, usually seen in Bright's retinitis. The conjunctiva was œdematous and the eyes were immovable; in the right eye a detachment of the retina was present; the patient had general anasarca, with albumen in the urine. She was seen by Dr. Holmes six years later, and showed in the left eye several light-colored patches, atrophy of choroid, bordering the disk. Could read Jaeger No. 1 at ordinary distance. In the right eye there was atrophy of the choroid, and, at the site of the former detachment, a long deposit of pigment. She had a central scotoma, and V. = $\frac{1}{3}$. The patient was totally blind for three weeks, and entirely color-blind for three months. In strong contrast to this is a case reported by Brecht, of Berlin, referred to by Loring in his paper (*loc. cit.*), in which separation of both retinæ occurred during gestation, and where readjustment of both took place after a premature birth, which occurred without any artificial intervention. In January, 1863, Mr. Lee (*loc. cit.*) saw a young lady in the third month of her pregnancy. She was suffering at that time from sensitiveness in the region of the uterus, sickness of the stomach, and general nervous irritability; the pulse, however, was not very rapid, and there was no symptom to excite alarm. On March 21st, two months later, he received a note from Mr. Bowman, desiring a consultation, as the patient had consulted him for defective vision. "The urine was loaded with albumen, and there was destructive disease going on in the coats of the eye." As the patient was in the sixth month of pregnancy, and seemed to be threatened with convulsions, and especially as the symptoms became urgent in the following three days, premature delivery was proposed by Mr. Lee, as he believed the affections of the kidneys and eyes arose from the pregnancy. Before, however, having recourse to this, it was considered proper to have a consultation with Dr. Robert Fergurson, who thought it unadvisable to induce premature labor, chiefly on the ground that the life of the child would necessarily be sacrificed. It was determined, on account of this advice, not to interfere, but to wait and see what course the disease would take. On April 10th, or three weeks later, there was an attack of convulsions, and as these were sufficient to excite apprehension that fatal puerperal convulsions would take place, it was considered proper, after a second consultation, that premature labor should be induced immediately. This was successfully performed, and, with occasional drawbacks, the patient continued to recover for the next ten days, when she could distinctly see the "figures on the dial of a watch."

Cases of this kind in which the intervention of nature, by producing premature delivery, has shown good effects upon the impaired eyesight, by removing the cause, might be increased in number, but we turn now to those in which the production of premature labor was done upon the advice of an oculist, for the purpose of restoring or improving vision alone.

Moore (*loc. cit.*) reports the following case: A German woman, aged forty-eight, pregnant with the twelfth child, has never had any ocular symptoms during previous pregnancies. She said that, three weeks before, she had had a chill, and thought she had taken cold; since then she has not felt so well. Shortly after this chill, she had had impairment of sight in each eye; although not completely blind, yet nearly so. She came under Moore's notice, January 2, 1881, when she was anæmic; no anasarca; urine contained about one-third albumen, and some epithelial casts. The ophthalmoscope showed the media clear, the retina much swollen, and neuro-retinitis, with exudations and hemorrhages well marked, more especially in the macula of the left eye. R. V. $=\frac{1}{70}$; L. V. $=$ fingers at one foot; the field of vision so much narrowed that the patient was unable to walk alone. Upon Dr. Moore's advice, the patient was transferred from the Eye Infirmary to the New York Infirmary for Women and Children, on June 5th, where premature delivery was brought on in the eighth month of pregnancy, of a still-born child. By June 30th there was only a trace of albumen, and vision had very much improved. The patient's vision, October 8th, was $\frac{20}{50}$ in the right and $\frac{20}{70}$ in the left eye, at which point it has been maintained.

A case in which the result obtained from induction of premature labor to save the sight alone, where the result was even better than in the foregoing, was seen by the writer in consultation with Dr. Arango, of this city, November 11, 1885. The patient was a multipara, aged forty, in the seventh month of pregnancy, whose sight was so much impaired that she could scarcely find her way about; V. $=\frac{20}{200}$ $(\frac{1}{10})$, the normal in each eye. The ophthalmoscope showed neuro-retinitis, whitish exudations scattered over the fundus, especially in the macula, and numerous hemorrhages. With the exception of albumen in the urine, there were absolutely no other evidences of disease of the kidneys. The immediate induction of premature labor was advised, under the belief that if the patient were allowed to go on to full term she might become irrevocably blind. After a delay of nearly three weeks, her sight becoming still worse, this was done by Dr. Arango, on November 30th, and she was delivered of a still-born child, which had probably been dead some time. January 6th, of the succeeding year, a little more than five weeks after the operation, the patient came to my office. I found V. $=\frac{20}{70}$. There was very great improvement in the retina, although still some neuro-retinitis and exudations. The improvement in vision from this time on was such that she never came to see me again, and Dr. Arango writes, upon recent inquiry, that her sight is perfectly restored.

At a meeting of the New York Ophthalmological Society, April 11, 1887, Dr. Callan reported the case of a woman, aged twenty-three, and married. The previous August she was within two months of full term, when she became entirely blind. Premature labor was induced, and three days after she could see large objects. Two months later she had entirely recovered. She then thought she was pregnant again. V., R. E. $=\frac{20}{40}$; L. $=\frac{20}{70}$. Nerve atrophic, with white spots in the region of the macula, and she thought her sight was failing. Dr. Callan advised her to wait two months before doing anything, and asked the opinion of those present. Dr. Webster thought Dr. Callan's advice was good, and said it was like a case that he saw in consultation with Dr. Laurence Johnson in the second or third month. In the eighth month the patient had convulsions, lasting all one night; in the morning she was blind in both eyes. The ophthalmoscope showed absolutely no changes. It was probably due to uræmic poisoning. Dr. Webster then advised premature delivery. It was done within twenty-four hours. The child lived and the mother recovered; probably vision, too, was restored, although the report does not say so. Dr. Cocks said he had also reported three or four cases, and thought the prognosis was good where there is no retinitis albuminurica. Dr. Callan said that Dr. Holmes, of Scarborough, had reported a case like these, and that in the case which he had himself reported there were no doubt changes of an inflammatory nature in the retina.

Is not the lesson to be learned from these cases so clear "that he who runs may read?" Here we have cases in which the patients were allowed to go to full term, in some instances through successive pregnancies, with serious impairment of sight, and in some they became blind; others suffered permanent impairment of their sight; again, premature labor without interference occurred, with the immediate improvement of vision, while, again, in the cases where, from the classical one of Loring down to the ones more recently published, in which the induction of premature labor was resorted to, the sight was always improved in the most unpromising, and in the more favorable ones fully restored. The prognosis in all these cases, especially where there are changes in the retina, will no doubt be modified by the pre-existence of chronic nephritis; in fact, it is held by some observers—Frerich and Braun, especially—that pure puerperal convulsions, presumably also therefore, neuro-retinitis, occurs only in pregnant women already suffering from Bright's disease. This view, however, is not concurred in by Seyfert, of Prague, and many others. Be that as it may, in the cases where chronic nephritis is present, the prognosis both for life and vision is worse, for the removal of the fœtus does not cure the kidney disease, and everyone engaged in ophthalmic practice will bear me witness how fatal the prognosis for life is in chronic Bright's disease with neuro-retinitis. That, on the other hand, so many cases in pregnant women with albuminuria and retinitis get well, would seem to be a forcible argument against this opinion. Does not the argument seem a strong one, that in all those cases in which there are changes going on in such delicate structures as the optic nerve and retina, the danger of their being destroyed and blindness resulting is rendered greater by letting the labor go on to full term and waiting until very much more damage is done?

It seems as though nature herself attempts to guide us to the proper course to pursue, for it must be noticed how often the occurrence of premature labor takes place without surgical interference, and how much better the results for vision have been than when labor went on to full term. Why should not we anticipate this action of nature, especially in the last months of pregnancy, when the child is still viable? Life is often endangered when vision is, and when this is the case there can be no doubt as to the weight of authority among obstetricians being in favor of abortion or premature labor. Is not death itself preferable to blindness, and what woman, left her choice between the alternatives, would choose to become a mother at such a cost? But there are cases like those of Loring and others, in which the impairment of vision comes on earlier in gestation, and Loring points out that they are of more frequent occurrence than is generally supposed, from which circumstance the responsibility becomes infinitely greater. In these cases the impairment begins early, and continues to grow worse throughout the progress of gestation; and these symptoms recur in successive pregnancies, until eventually total blindness is the result. Dr. Howe, of Buffalo, N. Y.,[1] in an analysis of cases occurring over a space of fifteen years, says: "These tend to show that when vision begins to be impaired only in the last two weeks of pregnancy, recovery follows almost invariably. [See my case.] Of those described as being in the eighth month, or thereabouts, when the retinitis commences, not one-half recovered, and several did not materially improve. Again, where this began earlier than was estimated, as the middle of the seventh month, when nature did not interfere by bringing on a miscarriage, and when the patient escaped with her life, it was only to remain blind forever afterward."

With such figures and facts before them, who can but concur with Loring that in extreme cases, where the sight is either lost or the risk of its loss is imminent, the production of abortion is justifiable, and even demanded.

One of the most important questions in this discussion is the medico-legal one. This is so ably met by Dr. Loring that I cannot do better than quote what he says on the subject. The moral question which he refers to I shall pass by in silence. "From a legal point of view, it is hard to conceive that there can be but one opinion, and that is in favor of the operation, when the circumstances are such as to demand it. The law states that premature delivery shall not be performed except for the preservation of the life of the mother or the child, and it is precisely for the 'preservation of life' that it would be done when the eyesight is threatened, for the one is part and parcel of the other; and in operating to save the sight we are operating to save life. Thus Simpson, many years ago, declared, and the opinion is universally upheld to-day, that symptoms such as headache, giddiness, and derangement of sight are merely premonitory symptoms of puerperal convulsions, and when they are associated with albumen we may be certain of the liability of our patient to the supervention of convulsions. Moreover, it so happens that the derangement of vision occurs at a time when, as Graefe puts it, 'the prognosis for life is even worse than for sight.' Given, therefore, a pregnant woman with loss of vision or organic lesion of the retina or optic nerve as the prominent or even sole symptom, no one can say that a series of convulsions may not set in at any moment which will carry everything before them, including not only the life of the child, but also that of the mother."

It is with no desire to encourage license in the production of abortion or premature labor, which many women only want the slightest excuse to consent to, and which, alas! some unscrupulous physicians are too ready to advise, but in the firm belief that the threatened loss of one of the noblest of our faculties, the sense of vision, should be considered to be of the same importance as the other symptoms which are said to more directly threaten life, and to justify such a serious procedure as the induction of premature labor, that these lines are written.

From the facts now before us, and the cases referred to, we summarize the following conclusions:

1. That in all cases of pregnancy it is not only desirable to examine the urine from time to time for albumen, but also to examine the eyes with the ophthalmoscope, even in a routine manner, since, as Loring points out, and as is well known to oculists, "a large percentage of cases having lesions of the optic nerve and retina either have none or make no complaint of loss of vision, but which may lead, after a long interval, through the secondary or atrophic state to complete blindness;" the fact, too, that varying degrees of blindness do not usually appear until near the end of pregnancy does not show that the retinal lesion may not already have been in existence for some time, and that the timely examination of the eyes might not have saved sight and even life. Moreover, it is known that the evidences of disease of the kidneys not infrequently show themselves in the eye before they do in the urine.

2. In uræmic amaurosis, without changes in the eye visible to the ophthalmoscope, even should the usual accompanying symptoms, such as dizziness, nausea, and threatened convulsions, be absent, their supervention is soon to be feared and the induction of premature labor is indicated, without waiting until the life as well as the sight of the patient is in danger.

3. In neuro-retinitis, with grave organic lesion of the retina and optic nerve, sight impaired, and the loss of vision progressing, especially in the last months of pregnancy, and the child (if not dead from the effects of the kidney disease) may be viable, it is not only justifiable, but urgently demanded, that premature labor be resorted to. In some rare instances, where it is evident that to wait until this time would be to doom the patient to blindness, it should be done even in the earlier months of pregnancy.

4. In those instances in which in one pregnancy failures of vision have occurred which have remained permanent, abortion in the following pregnancies in which symptoms of failure of vision again occur may be rendered necessary. This conclusion is meant to cover cases like Loring's, whether it be finally ascertained that they are dependent upon kidney disease or not; the weight of the responsibility of the decision in these cases must lie with the oculist, however, since he alone, from both the objective and subjective symptoms, can conclude whether the gravity of the case warrants the operation.

5. Women having once suffered loss of or impairment of vision during pregnancy should have the danger of again becoming so, and the relation of cause and effect, fully explained to both themselves and their husbands.

THE USES OF METHYLAL.—Dr. Richardson has published his views on methylal in the *Medical Press*, November 2, 1887. He says that he has often given it in doses of from one to four drachms, combining it for the sake of the flavor with orange-flower syrup and adding water (proportions, methylal, ʒ j.; syrup of orange, ʒ ss.; water, ℥ ss.). Administered in this way by the stomach, it possesses hypnotic and antispasmodic properties of considerable value, and its grand service will be in the treatment of spasmodic and painful affections, such as asthma, angina pectoris, colic, and tetanus. Its readiest value will probably consist in its use as a menstruum for other substances of the same therapeutical action. He concludes his article with the following summary: 1. Methylal is hypnotic and antispasmodic. 2. Its action lies between ethylic alcohol and ethylic ether. It may be looked on as a volatile alcohol, and resembles closely pure methylic alcohol in action. 3. It can be administered by inhalation as vapor, by hypodermic injection, and by the mouth in aqueous solution. 4. It reduces arterial tension, and by local action excites glandular activity. 5. The sleep it induces is not profound unless the dose be excessive. It is quickly eliminated, and leaves no serious effects. It causes no vomiting or stomachic disturbance. 6. A fatal dose by inhalation kills by complete relaxation of the muscular fibres of the heart, leaving the heart distended with blood and the vascular organs intensely congested. 7. It combines with ether, alcohol, amyl nitrite, and many other remedial agents with which it acts in concert, while it equalizes their action by reason of its own solubility. 8. Its tendency is to maintain the fluidity of the blood, and it may therefore be of service in combination with ammonia. 9. It promises to yield a safe and effective anæsthetic mixture in combination with ether. 10. It reduces the animal temperature, but not to the same degree as common alcohol. 11. Used as an anodyne, it passes out of the body without producing organic injury, when not often repeated. 12. But, like all bodies of its class, it must be given in increasing quantities in order to keep up its effects, and it would soon yield evil as well as good by its habitual use in the community at large.

---

Clinical Department.

A CASE OF MYXŒDEMA.

By ANDREW WATT, M.D., C.M.,

LAWRENCE, MASS.

The insidious symptoms and unsatisfactory treatment of that rare disease, myxœdema, has led me to report the following case lately under my own observation.

Mrs. M——, aged thirty-six, IV.-para, Scotch parentage. The family history was decidedly neurotic, as both an uncle and a brother had been under treatment in insane asylums.

The patient was well developed, and had dark hair and a sallow complexion. Over each malar bone there were vascular patches, and there was also considerable puffiness about the eyelids. The appearance of the physiognomy seemed to indicate some chronic kidney disease. There were two moles on the left side of the neck, one on the back of that shoulder, and one on the deltoidal prominence of the left arm. Apparently the thyroid body was normal.

The hands were "spade-like." The thoracic and abdominal viscera appeared to be normal, except that the action of the heart was weak, and the pulse-beat usually from sixty to sixty-five per minute. The catamenial flow was irregular and scanty, and the patient complained of chronic constipation.

Urine, sp. gr. 1.005, acid and free from albumen, the quantity about natural, and color always pale. Both legs were œdematous, but the left pitted more than the right. The pitting was distinctly characteristic of the disease, for it only appeared after a prolonged firm pressure, so very different from what is seen in ordinary œdema.

The integument was dry, translucent, and inelastic. The patient's speech was slow, the voice having a snuffling, nasal twang and a falsetto character. The temperature in the right axilla was normal, but in the left it was 97.4° F.

She complained of being very easily thrown off her balance and falling down, and she could scarcely walk a single step in the dark. She stated also that she suffered from occasional profuse perspirations.

No medicine appeared to have any good effect on the disease, which she said had begun six years before.

Myxœdema differs from sclerema only by being a progressive general malady, and there cannot be a doubt that the central nervous system is largely implicated from the first, because in all cases there is some mental disturbance, ranging from simple irritability of temper or depression of spirits up to aggressive mania and fatuity.

But the peculiar nervous symptoms characteristic of this disease are progressive, increasing with the severity of the disease. In my opinion the slowness of the transmission of nervous impulses and sensations is owing to the disturbance of the peripheral nerves from the œdema.

This woman had had a most unhappy married life, and the continual ill-treatment received from her brutal husband, combined with her sensitive, nervous disposition, had, she was sure, greatly aggravated her disease.

DIABETES MELLITUS IN AN INFANT.

Dr. W. H. Deane, of Blandford, Mass., reports the following case: "On November 20, 1887, a little girl, aged one year and three weeks, was brought to my office by her mother, who said that the child was somewhat fretful at night, seemed rather thirsty, rolled its head while sleeping, occasionally wakened from sleep with a sudden scream, and, she thought, was passing more urine than it should.

"The child was bright, fairly well nourished, with no marked evidences of any serious trouble. The child was, with some difficulty, cutting several teeth, and I considered the symptoms as due to that cause. The increased secretion of urine, which the mother had referred to, I thought very little about. In a very few days I was called to see the child, and found it in about the same condition as when at my office, except that it had begun to show some emaciation. I then asked for and, after some difficulty on account of the extreme youth of the patient, obtained a specimen of the urine, which I found, by each of the copper, indigo, and fermentation tests, to contain a considerable amount of sugar—about ten grains to the ounce. I immediately began administering codeia, and restricted all sugar from the diet. Nevertheless, emaciation rapidly progressed, digestive disturbances became more or less troublesome, the rolling of the head and crying out suddenly in sleep continued, and on January 4th the child passed into a well-marked condition of diabetic coma, and succumbed in twenty-four hours. Under my treatment the amount of urine diminished somewhat, although the specific gravity remained at 1.040, and the sugar was continually present.

"The extreme youth of the patient, the rapidly fatal termination, and the continued presence of symptoms of brain-irritation, have caused me to regard this case as one quite singular."

TOXIC EFFECTS FROM SMALL DOSES OF POTASSIUM CHLORATE.

Dr. A. F. Fuchs, of Fredonia, Wis., writes: "A robust male adult, aged forty-eight, was ordered to use a saturated solution (1 in 20) of chlorate of potassium as a gargle for diphtheria. He was directed to take a very small swallow, three times in twenty four hours, directly from the bottle, in addition to gargling every two hours. After taking the fourth dose, the urine was noticed to be dark red, and a messenger came to inform me. The chlorate was discontinued, and in thirty-six hours the urine was of ordinary appearance.

"Macroscopically, the urine presented every appearance of a hemorrhage from the kidneys, but it was much darker than in any case of hæmaturia I have seen. Analysis showed the presence of blood. There can be no doubt that the chlorate was the cause. No other drug was given immediately before, or after, or conjointly with it. Three doses of calomel had been given, the last one six hours before beginning the chlorate. The patient affirmed positively that he had not taken more than a teaspoonful at a dose, but, allowing four times that quantity, we would have forty-eight grains producing toxic symptoms."

An Accouchement in a Railway Closet.—Dr. William Osler is writing stories to the *Canada Medical and Surgical Journal*, and this appears in the latest issue of that excellent periodical: "A young woman about twenty-eight years of age, well developed, of medium size, had had two previous labors, which were not difficult. She had expected her confinement in a week or ten days, and had got on the train to go to see her husband, who was working 'down the track.' Having a slight diarrhœa she went to the water-closet, and while on the seat labor pains came on and the child dropped from her. Hearing a noise and groaning, the conductor forced open the door and found the woman on the floor in an exhausted condition, with just strength enough to tell him that the baby was somewhere on the track, and to ask him to stop the train, which was running at the rate of about twenty miles an hour. The baby was found alive on the side of the track a mile or more away, and with the mother was left at the station where I saw her. She lost a good deal of blood, and the placenta was not delivered for some hours."

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, January 28, 1888.

THE INFLUENCE OF MODERATE DRINKING ON HEALTH.

UNDER the title of "The Influence of 'Nipping' upon Health," Dr. Harley, the English hepatologist and nephrologist, discusses, in the January number of the *Provincial Medical Journal*, the injurious effects of drinking alcoholic beverages "in moderation." He says that the majority of men are moderate drinkers, and, as a consequence, most of one's patients belong to this class. Dr. Harley is right in stating that the effects of alcohol taken in excess are universally known to physicians. But his other statement, that very little has been written on the consequences of drinking in moderation, can only be accepted in the qualified sense of "comparatively little." Be this as it may, the figures published by him, as taken from the Registrar-General's report, are certainly rather staggering. Comparing the mortality tables of men exposed to the temptation of frequent "nipping" with those of men not similarly exposed, the result is "startling in the extreme, more particularly as regards the proportion of liver diseases." For it would appear that the rate of mortality is six times greater among those whose business is practically inseparable from "nipping," than among those representing all the other industries combined.

It appears further, that, after the liver, the kidneys, the heart, and the nervous system become most frequently affected in moderate imbibers. Dr. Harley says that "it is not difficult to understand why the liver, of all organs in the body, should be the most affected by 'nipping,' when it is remembered that almost every drop of alcohol taken into the stomach is absorbed by the branches of the portal veins, is conveyed directly to the liver, and has to filter through its tissues, ere it can get into the general circulation, and by it become distributed to the other organs of the body." He also showed, so long ago as 1853, that the mere injection of alcohol into the portal vein in dogs is sufficient to disorder the hepatic functions to such an extent as to cause the animals to become diabetic in the short space of from two to three hours.

That the kidneys suffer less than the liver is probably due to the fact that less alcohol reaches them than the former. Nevertheless, alcohol is, in part, eliminated through those emunctories, and Harley claims to have obtained "pure alcohol" from the kidneys of persons who have died intoxicated, by the simple process of distillation.

According to the author, "the only tangible reasons, however, that we as yet possess for alcohol disordering the renal function exist (1) in the fact of its elimination causing extra work; and (2) that alcohol increases the renal circulation, just as it increases the circulation elsewhere, and no doubt at the same time causes a corresponding increase in the diameter of the renal blood-vessels by engorgement, and consequent pressure on the inter-vascular tissues."

As regards the bad effect of "nipping" upon the heart, it consists in inviting disease in the predisposed, as well as in augmenting disease which already exists.

Finally, with regard to the nervous system, Dr. Harley believes that alcohol taken in small quantities at a time, but frequently repeated, acts deleteriously by keeping the blood-vessels on the stretch, by engorging them, and causing them to press upon the nerve-cells and fibrils. This interferes both with the proper performance of their functions and with nutrition.

The nerves also suffer indirectly through the action of alcohol on the blood. For Harley has found that, even in the small proportion of five per cent., alcohol "exerts a powerful chemical effect on blood, so powerful as to entirely derange one of its most important functions—namely, the function of respiration. The alcohol seems to act like an asphyxiant, inasmuch as it not alone diminishes the power of the red corpuscles to absorb oxygen, but to exhale carbonic acid, and that, too, in the same way (though to a somewhat less extent) as morphia does. This peculiar chemical action of the alcohol on the blood nerve-pabulum may be thought to give a reasonable explanation of the paralyzing action of alcohol upon the nervous system, seeing that oxidation is the motor power of all vital action, and in direct proportion to its activity are the manifestations of life accelerated or retarded. Every breath we draw, every movement we perform, every thought we think, is but the outcome of the transformation of matter under the influence of oxygen. If, then, it be true as above shown, that alcohol possesses the power of preventing the constituents of the blood from being properly oxidized, and thereby fitted for the purposes of nutrition, it is easy to account for its producing a chain of neurotic symptoms terminating in coma and death."

THE SCHOOL-AGE AND SCHOOL-HOURS.

DR. C. W. CHANCELLOR, of the Maryland Board of Health, has recently given an interesting summary of those sanitary requirements which relate to our school-system and the public education of children (*Gaillard's Medical Journal*). So much ignorance still prevails regarding this matter, and our school-systems are yet so far from what sound educational principles demand, that articles like this of Dr. Chancellor should not go unnoticed.

The writer, after taking up the subject of school-house construction and site, discusses the question of the age at which education should begin. He cites a number of authorities, from Aristotle to Hufeland, all tending to show that the school-work should not begin until the eighth year. It would not be difficult to find authorities supporting a somewhat different view, and it cannot be asserted that the old New England school-system, which took in the children at the ages of four to six, was a pernicious one. The not very high authority of Spurzheim is quoted in support of the view that "precocity is almost always a disease." It is "an envious frost, which nips the blossoms because they appear quickly," and such statements regarding precocity are quite untrue. Nearly all men of genius, and very many men of talent, have shown decided precocity.

It is claimed that children whose systematic studies begin at eight years of age get along just as fast as others, and at, say sixteen, know just as much as if they had begun at six. Often this is true, but it has not, we think, been demonstrated to be the rule. Education, *i.e.*, mental and physical training, may begin, as Quinquillian recommends, at the third or fourth year. But while our schools are arranged as at present, it may be wise to accept the modern view, that the school-age should begin at seven or eight.

Ribot has shown that capacity to fix the attention is a characteristic of more civilized and intellectual people. So it is also of more mature minds. The infant has no such power; the child of three wearies after a few minutes' effort at following some train of thought or memorizing process.

According to Dr. Newell, "for children of ten or twelve years the capacity for bright and voluntary attention is exhausted by four varied lessons requiring mental effort of half an hour each, with intervals of relief in the forenoon. In the afternoon this capacity is reduced one-half. Two hours in the forenoon, and one hour in the afternoon, is as long a time as children can be profitably employed in school."

Dr. Chancellor supports this view, and advocates eighteen hours a week as the limit for school-children under twelve. Baginskey, author of a German work on school hygiene, takes the same view, and in demonstration of its effectiveness it is alleged that half-time pupils in the English schools learn as much as the children who are in school the full number of hours.

It would be better, according to Dr. Chancellor, from a purely hygienic point, to make Wednesday the weekly holiday rather than Saturday, and to have examinations occur at the beginning of a school-term than at the end. While this latter seems hardly practicable, the evils of the present system are undoubted, and a dividing up the examinations would certainly be more satisfactory and less injurious to the health of the children.

CARDIOCENTESIS.

Dr. I. Bruhl, of Paris, has given a history of the operation of cardiocentesis, with reports of cases in which this operation has been performed, and a general summary of the present condition of the question (*Le Progrès Médical*, Nos. 52 and 53, 1887). M. Bruhl states, correctly, that the mode in which puncture and aspiration of the heart acts is a double one. First of all, it does exactly what bleeding would do, but it has the advantage that it withdraws blood from the venous circulation after the heart has stopped beating, or is beating so feebly that there could be no blood drawn from the veins. In the second place, the puncture of the heart by the needle acts as a stimulus to the heart-muscle. Cases have been reported in which the heart has been stimulated after its apparent paralysis.

M. Bruhl's conclusions, which, it must be remembered, are based more on a study of the literature than on practical experience, are: That cardiocentesis is practicable, and, in most cases, is not dangerous. M. Rendu, however, is cited as stating that "a wound of the heart is so great a responsibility to assume that one should avoid it at any price." Such a caution may be wisely kept in mind, though numerous facts attest the harmlessness of puncturing the heart with needles.

In order to puncture the right auricle, the aspirating needle is to be passed into the third intercostal space, close to the right edge of the sternum.

To puncture the left ventricle, the needle should enter the fourth intercostal space, near the left edge of the sternum. The puncture of the ventricle is, as M. Bruhl correctly states, preferable to that of the auricle.

The indications are naturally a paralysis or paresis of the heart, with dilatation and over-distention of its cavity.

KARYOKINESIS.

The term "karyokinesis" was introduced into embryological science, some ten years ago, by Schleicher, and it has evidently come to stay. There is a certain easy rhythmical flow about this word which endears it to those who have once rolled it over their tongues, or felt its stately prosodical impact on their acoustic organs. This has been an element, no doubt, in perpetuating it in scientific language. So far as we can learn, no one has even attempted to give an equivalent or a substitute for it.

Karyokinesis is the term applied to a process of indirect division of cells in their growth and multiplication. It is quite generally agreed that the cell-body and nucleus are both of a complex structure, being made up of a fine fibrillary net-work, with a homogeneous substance in its meshes. This cell may divide directly by simple cleavage, the nucleus usually dividing first (Landois); or there may be an indirect division, or karyokinesis, the process being then limited primarily to the nucleus, as shown by the term *karyon*, nucleus, and *kinesis*, movement.

This indirect division is shown by the development in the nucleus of thread-like patterns, which are known as the karyokinetic figures. There is, as described by Dr. James (*St. Louis Medical and Surgical Journal*), a chromatic figure which takes up the coloring matter and the nucleoles, and the achromatic figure, which is colorless and composed of much finer fibrillary threads.

In the process of indirect division the threads and fibrillæ arrange themselves in a succession of different forms. These have a tolerably definite order, and have received different names. There is first a convolution of fine threads. These arrange themselves in the form of a rosette or star. The fibres finally arrange themselves about two poles or new circles, forming a double star. Between the two is a substance called the equatorial plate. Each of the polar groups gradually develops into a new nucleus, the cell divides at the equatorial plate, and two new cells are formed. In rare cases three, or even more, cells may develop from the original one. In some cases the process results only in multiplying the nuclei, the cell-body not being divided, and in this way the origin of multinuclear cells is explained. Karyokinesis is observed not only in animal, but vegetable life.

A CURIOUS AFFECTION.

In some parts of Japan a strange disease prevails, which is known popularly, from its most prominent symptom, as the "head-drop." The symptoms of the affection, as detailed by Dr. K. Nakano in the *Sei-I-Kwai Medical Journal* for November, 1887, are as follows: There are no prodromes beyond headache and slight mental uneasiness coming on a few hours before the attack. The disease begins quite suddenly with a seeming paralysis of the posterior neck-muscles, so that it is impossible to hold the head erect, and it falls forward with the chin against the sternum. In some cases there is congestion of the conjunctivæ, the pupils are dilated, and monocular or binocular diplopia is complained of. The tongue becomes stiff, the speech slow, and swallowing is difficult. The muscles of the lumbar region are very weak, and the patient walks only with the greatest difficulty. In the most severe cases the legs become paralyzed and anæsthetic. The urine, on standing, throws down a white sediment which is not redissolved by heat or acid. There is no albumen, but occasionally sugar is present.

The duration of the attack is usually from a few hours to several weeks, or even two or three months. The disease is apt to recur in those who have been once attacked, sometimes within a short period. The treatment seems not to be very satisfactory in its results. The disease disappears spontaneously, and its duration is so variable that it is difficult to say what effect treatment has upon its course. Dr. Nakano mentions as a curious fact that an attack is very apt to come upon one when he is hungry, and in such a case a hearty meal will cut it short at once.

The author regards the affection as of malarial origin. It occurs only in damp valleys where but little sunlight penetrates, and attacks exclusively farmers and those engaged in similar pursuits. Of the 63 cases observed, 37 occurred in men, and 26 in women. In addition to the unfavorable conditions of soil and climate, the fact that the inhabitants of the district live generally on poor food and drink bad water may be of some etiological significance. The disease occurs at all seasons, but especially in the late spring and early summer. When the disease prevails it does not attack all the people in a community at the same time, but seems to be more or less confined to single families. If one person in a family is attacked, the other members are usually attacked also within a short time, but the affection does not seem to be spread by contagion. Those who have suffered from frank attacks of malarial fever do not appear to be subject to head-drop.

The disease is not fatal, and consequently no opportunity has occurred to study the pathological lesions. But the symptoms would point to some temporary affection of the cord, due, possibly, to the action of the malarial poison.

THE MODERN TREATMENT OF URETHRAL STRICTURES.

Legitimate criticism on the evils of specialism applies only to the practice, not to the scientific work done in special fields. An illustration of what has been accomplished in genito-urinary surgery by the diligent ingenuity of its followers, is furnished in a recent article by Dr. F. S. Watson (*Boston Medical and Surgical Journal*, 1887, No. 26), entitled "A Comparison of Gradual Dilatation, Divulsion, Internal and External Urethrotomy, in the Treatment of Urethral Stricture." This article, taken in connection with the discussion which followed it before the Suffolk District Medical Society, shows that the general methods of practice in the treatment of strictures have become quite uniform, and that the labors of the specialist have developed the art of treating strictures so that the general practitioner can carry it out in most cases, when he has acquired a little technical skill.

The three accepted methods of treating organic urethral strictures are by gradual (or rapid) dilatation, divulsion, and urethrotomy.

Gradual dilatation is admitted to be the least efficacious, and is rarely resorted to except as a temporary or palliative measure, especially in strictures of the anterior urethra. In the deep urethral strictures, owing to its comparative safety and to the disinclination of many patients to an operation, it is oftener employed. But no surgeon promises a cure from its use. The method, according to Dr. Watson, is responsible for more bad urethras (false passages) than anything else, for the steel sound has a powerful leverage and the chronically inflamed mucous membrane is easily torn. We think, however, that harm only occurs because the clumsiness and carelessness of many patients, and perhaps a few physicians, are almost beyond belief.

Divulsion is an operation of which the mortality, according to statistics collected by Watson, is from one to five per cent. This represents the operation as much more dangerous than it really is to persons with sound kidneys and bladders. Except sometimes in early strictures, divulsion is believed never to be curative. Still, the best results have not been gotten from it by many, because the operation has not been followed by thorough dilatation. The theoretical objection that the tear made by divulsion is worse than the clean cut of the urethrotome, does not always hold good, as was shown in the discussion later by Dr. Cabot.

Internal urethrotomy is acknowledged to be, on the whole, the best and surest way of treating organic strictures not in the deep urethra. In a small percentage of cases, permanent cure is obtained. The danger is about the same as in divulsion. For strictures of the deep urethra external urethrotomy is very generally believed to be the best, and even the safest method, although gradual dilatation and divulsion are sometimes indicated.

Dr. Watson states his conclusions as follows:

"1. All strictures anterior to five inches are best treated by internal urethrotomy. Dr. Otis' operation yields the most enduring results.

"2. Divulsion should be rejected as an operation for stricture, unless it can be shown satisfactorily that, where carried sufficiently far, it yields as permanent results in as many cases as internal urethrotomy.

"3. Dilatation, where practicable, should be employed in strictures deeper than five inches.

"4. For strictures deeper than five inches not suitable for dilatation, external urethrotomy should be selected, and not reserved for an emergency operation only."

News of the Week.

DR. A. D. ROCKWELL.—A Professorship of Electrotherapeutics has been established in the New York Post-Graduate School of Medicine, and the position has been offered to and accepted by Dr. A. D. Rockwell.

SECTION ON PRACTICE, NEW YORK ACADEMY OF MEDICINE.—At the last meeting of this Section, held January 17th, Dr. R. C. M. Page was elected Chairman, and Dr. George B. Fowler, Secretary.

THE NEW YORK CANCER HOSPITAL (Eighth Avenue and 106th Street) has received a donation of $25,000 from Mr. John Jacob Astor for the endowment of five additional beds in perpetuity.

THE ALUMNI OF THE BELLEVUE HOSPITAL MEDICAL COLLEGE will have their annual dinner at the Buckingham Hotel, Fiftieth Street and Fifth Avenue, on February 14th, at 8 P.M.

THE AMERICAN MEDICAL ASSOCIATION MEETING.—The organization of the next meeting of the American Medical Association at Cincinnati, O., is being satisfactorily perfected. The Central Committee of Arrangements has been having weekly meetings, and has done much toward the work. Music Hall, a most excellent place for the meeting, has been secured, and all meetings will be held under one roof. Transportation will probably be one and one-third fare for the round trip. The Chairman of the Committee of Arrangements is Dr. W. W. Dawson, corner Third Street and Broadway, Cincinnati. Chairman Committee of Receptions: Dr. J. T. Whittaker. Finance: Dr. S. C. Ayres. Exhibits: Dr. J. C. Culbertson. Transportation: Dr. William Judkins. Invitation and Printing: Dr. G. A. Fackler. Halls: Dr. B. Stanton. Printing: Dr. J. Ransohoff. Registration: Dr. J. M. French. Arrangements are making for a reception at the Art Museum in Eden Park and a supper at the Highland House on the hill-top. A banquet will also be given, and a concert by the Apollo Club is expected. There will also be numerous other things to entertain and interest. Cincinnati being very central in its location, it is expected that the attendance will be larger than ever before.

MATERNITY HOSPITAL.—Dr. H. C. Coe has been appointed Obstetric Surgeon to the Maternity Hospital, to fill the vacancy created by the resignation of Dr. Partridge.

A NEW FORM OF FEVER IN TEXAS.—Dr. A. W. To and writes to the *Southern Practitioner* that there is a strange fever prevailing in Texas, somewhat resembling typhoid, but not involving Peyer's patches, and not influenced by quinine. Dr. Ketchum, of Palo Pinto, Tex., has also referred to this disease in *The Medical Age.*

BERLIN DOCTORS AND THE CANCER-BACILLUS.—A Berlin correspondent of the *Wiener Med. Wochenschrift* writes that when three doctors meet now the subject of conversation is sure to be the cancer-bacillus, and if the three are German doctors there are four opinions expressed! One view, which is that held especially in Berlin, under the lead of Virchow, "the father of scepticism in medicine, especially as to discoveries not made by himself," is that of utter disbelief in the discovery of the bacillus. Others hold expectant views, while a small party, led by Guttmann, enthusiastically supports the discovery and the discoverer.

A NEW DISEASE affecting swine has been discovered by MM. Cornil and Chantemesse. It has heretofore been confounded with porcine measles (*rouget*). It begins like an infectious fever and ends with a fibrinous peripneumonia. It is almost always fatal. Its microbe has been isolated and cultivated.

GENERAL ANÆSTHESIA FROM COCAINE.—M. Lafont announces to the Académie des Sciences that the local application of cocaine to certain parts of the body will cause a general anæsthesia. The part mentioned as best showing this is the pharyngeal mucous membrane. The effect is probably inhibitory, as Brown-Séquard has shown.

MENTHOL IN PHTHISIS.—Rosenberg's method of treating phthisis by menthol-injections is highly praised by Dr. A. J. Belhag in the Edinburgh *Medical and Surgical Journal.* He makes a twenty per cent. solution in warm olive-oil and injects fifteen minims into the larynx and trachea. Two or three injections are made twice daily for about two months. Menthol-injections are useful also in nasal and pharyngeal catarrhs.

MODERN ANTISEPSIS is spoken of as "the glorification of dirt."

IT IS A FACT known to neurologists that psychoses and neuroses may develop after gynecological operations, such as ovariotomy, Tait's operation, etc. Dr. Edward J Ill reports three cases of this kind in the *Pittsburg Medical Review.*

THE BROOKLYN HEALTH COMMISSIONER.—The new Mayor of Brooklyn, Mr. Chapin, has appointed Dr. John Griffin Health Commissioner of the city, in the place of Dr. Otterson. Dr. Griffin is a member of the Kings County Medical Society and of the Brooklyn Board of Education. He is a native of Ireland, forty-two years old, and came to this country in 1868.

SMALL-POX IN BROOKLYN.—Small-pox has appeared in Brooklyn, and up to date of writing about forty cases had been reported.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.—Dr. Charles McBurney read a paper on "External Perineal Urethrotomy as a Prevention of Complications after Operations upon the Urethra," which will appear in a future number of THE MEDICAL RECORD. The paper was discussed by Drs. Bangs, Abbe, and Otis, all of whom coincided in the views of the author regarding the importance of drainage, but they did not accept his view that all cases of urethral fever were due to absorption of septic material. Dr. Billington read a provisional report from the Committee on Hygiene.

THE LATE DR. WESLEY M. CARPENTER.—Dr. Daniel Lewis, at the last meeting of the Medical Society of the County of New York, read a memoir of the late Dr. Carpenter, and offered the following resolutions, which were adopted:

Whereas, In the wisdom of the Supreme Ruler, our distinguished associate, Dr. Wesley M. Carpenter, has been taken from our ranks at the very meridian of his usefulness;

Resolved, That we, as members of the Medical Society of the County of New York, hereby desire to record our appreciation of his long and faithful services as our Secretary;

Resolved, That in all things pertaining to his professional work we recognize in Dr. Carpenter's career among us a standard of life and a devotion to scientific medicine which place him among the most honored of our profession;

Resolved, That while admiring, as we do, those qualities most conspicuous in his character as a medical man, a much more intimate relation has been established between him and us, which renders his death a personal bereavement. Although time may mitigate our grief, it can never banish from our hearts the recollection of his kind and exemplary life;

Resolved, That these resolutions be spread upon a page of our minutes set apart for that purpose.

THE MEDICAL SOCIETY OF THE STATE OF NEW YORK —REDUCED FARES FOR MEMBERS.—All physicians wishing to attend the meeting of the New York State Medical Society, to be held at Albany, February 7th, 8th, and 9th, are informed that the New York Central Railroad Company have kindly consented to issue excursion tickets at the rate of a fare and a half, $4.65, the regular rate being $6.20. It is the intention of the majority of the delegation to go to Albany, February 6th, at 3.30 P.M. If a sufficient number can be obtained for that train a drawing-room car will be furnished for their exclusive use. Drawing-room fare, $1. All gentlemen who can arrange to go on that day and train are asked to notify the Secretary of the Delegation, Dr. Clarence C. Rice, 115 East Eighteenth Street, on or before February 6, 1887. Certificates for tickets can also be had by application to him.

THE DUTY ON SURGICAL INSTRUMENTS AND APPLIANCES.—The Georgia Medical Society has issued circulars to all the medical societies in the country, asking their co-operation in urging upon Congress the need of removing the tariff upon surgical instruments and appliances. The Society thinks the interests of humanity will be subserved by the removal of all imposts upon instruments and medicines, and that Congress can be best influenced by the separate action of all the medical societies of the country in concert; the attempt has been made by the actions of large bodies, such as State associations and the American Medical Association, and the like, but has failed, largely, as it thinks, because it was the action of representative bodies, and not of their constituencies, the local medical societies and individuals of the profession. Societies are asked to pass the following resolution: "*Resolved*, That the —— —— Society would urge upon Congress that, in the cause of humanity, the *import duty* should be removed from all medicines, medical and surgical appliances, and from everything used in the treatment or diagnosis of disease."

DERMATOLOGISTS may be a little disappointing in their therapeutics, like the rest of the profession, but when it comes to giving diseases names of real, rasping, polysyllabical stridulousness, they leave other specialists, including the author of Volapük, far behind. Dr. Hyde has recently reported three cases in which the patients were affected with symmetrical and recurrent or persistent tylosis of the palmar and plantar surfaces, accompanied by hyperidrosis, alopecia, bromidrosis, and a species of onychauxe, which the author supposed to be due to the same process in the skin which produced the callosities.

Reviews and Notices.

MANUEL DE MÉDECINE OPÉRATIVE DE J. F. MALGAIGNE, Professeur de Médecine Opérative à la Faculté de Médecine de Paris; Membre de l'Académie de Médecine, etc. Neuvième Édition par LEON LE FORT, Professeur de Clinique Chirurgicale à la Faculté de Médecine de Paris; Membre de l'Académie de Médecine. Première Partie. Opérations Générales. Avec 352 Figures Intercalées dans le Texte. Paris: Félix Alcan. 1888.

MALGAIGNE'S MANUAL OF OPERATIVE MEDICINE. Ninth Edition. By LEON LE FORT. First Part. General Operations.

THIS latest edition of Malgaigne's "Manual of Operative Surgery," revised by Le Fort, has been greatly enlarged by reason of the additions necessary to bring it up to the times. The first part contains sections on anæsthetics, surgical instruments and minor operations, general operations and prothetic apparatus. M. Le Fort is no friend of Listerism, so called, and devotes considerable space in the introduction to an exposition of his own views concerning the true cause of suppuration in wounds. He insists upon the absolute surgical cleanliness of instruments and hands, but does away with all antiseptic dressings as being cumbersome and useless. The book is profusely illustrated, the descriptions are clear and concise, and the work is a most trustworthy guide in all that concerns operative surgery, the question of antiseptic dressings alone excepted. The second part, treating of special operations, is to appear during the current year.

MANUAL OF CLINICAL DIAGNOSIS. By DR. OTTO SEIFERT, Privatdocent in Würzburg, und DR. FRIEDRICH MÜLLER, Assistent der II. med. Klinik in Berlin. Third Edition, Revised and Corrected by DR. FRIEDRICH MÜLLER. Translated, with the Permission of the Authors, by WILLIAM BUCKINGHAM CANFIELD, A.M., M.D. (Berlin). With Sixty Illustrations. New York and London: G. P. Putnam's Sons. 1887.

THIS little book contains very much that will be found of value to the student of diagnostic methods. The examination of the different organs is fully treated of, and the various tests employed in the analysis of the secretions and excretions of the body are described clearly and at all-sufficient length. Numerous illustrations serve to elucidate the text where necessary. For the student and hospital interne we know of no better book, and many older practitioners will find here methods described which were unknown in their student days, and which, perhaps, they have never learned for the want of just such a convenient little manual as this.

The Principles of Theoretical Chemistry. By Ira Remsen, Professor of Chemistry, Johns Hopkins University. Third Edition. Philadelphia: Lea Brothers & Co. 1887.

The third edition of this standard work has been somewhat enlarged and thoroughly revised. A brief and instructive chapter has been added, on matters pertaining to chemical affinity, and on the connection between constitution and chemical conduct.

Lessons in Gynecology. By William Goodell, A.M., Professor of Clinical Gynecology in the University of Pennsylvania, etc. Third Edition, thoroughly Revised and greatly Enlarged, with One Hundred and Twelve Illustrations. Philadelphia: D. G. Brinton. 1887.

The former editions of this treatise were well received by the profession, and there is no doubt that the new matter added to the present issue makes it more useful than its predecessors. The work can lay no claim to being a complete treatise on the subject of which it treats; but it embodies, in a very readable way, the views of its author on many topics of interest to the general practitioner, rather than the specialist, in this department of medicine.

The Physician's Visiting List for 1888. Philadelphia: P. Blakiston, Son & Co.

This popular visiting list has come to hand in its usual shape. For its small size it contains a good deal of information that is apt to prove useful to the practitioner.

Syphilis. By Jonathan Hutchinson, F.R.S., LL.D., Consulting Surgeon to the London Hospital, and to the Royal London Ophthalmic Hospital; Vice-President of the Royal College of Surgeons. Philadelphia: Lea Brothers & Co. 1887.

The author of this excellent little manual is a leading authority on the subject with which it deals. On perusing its pages one cannot fail to be struck with the fidelity of his portraiture of the varying phases and aspects of syphilis. Dr. Hutchinson is at times rather dogmatic; but, for our part, we prefer the unequivocal enunciation of personal views, to the unsatisfactory attempts, so often made, to reconcile opposing views in a weak-minded adherence to most opinions and a strong dissent from none. This brief clinical manual is bound to be welcomed by the profession, and we predict for it a wide popularity.

Dental Caries and its Prevention. By Henry Sewill, M.R.C.S., etc. Second Edition. 12mo, pp. 93. London: Baillière, Tindal & Cox. 1888.

The particularly interesting point of this elaborate essay is the influence of micro-organisms on the production of the disease. Mr. Sewill regards them as the pathogenic factor. The predisposing causes are those which impair the integrity of the enamel, such as the acids which are the products of chemical change and fermentation set up in the fragments of organic matter lodged upon the teeth, and perverted secretions from the mucous membrane. In the author's experience, not even one per cent. of children with a syphilitic taint have had the characteristic tooth condition, first identified by Mr. Hutchinson. The book is well written, and is a valuable contribution to odontological literature.

Hydrophobia: Pasteur's System. By Renaud Suzor, M.D. 12mo, pp. 231. London: Chatto & Windus. 1887.

The writer was sent by the Governor and Council of the island of Mauritius to study the Pasteur system at Paris. His narrative is accordingly descriptive rather than critical. The bulk of the volume is occupied with translations of Pasteur's communications to the French societies. Then follows a detailed account of the technique of the method. A short history of hydrophobia opens the book. It is well written, and is a compact *résumé* of the literature of the last few years on the topic.

M. Suzor coincides with the conclusions of the French *savant.* "The prophylaxis of rabies after bites is now an established fact."

Leçons sur la Thérapeutique de la Métrite. Par L. Martineau, Médecin de l'Hôpital de Lourcine; Vice-Président de la Société d'Hydrologie; Membre de la Société Gynécologique et Obstétrique de Paris; Membre Correspondant de l'Académie Royale de Médecine de Rome, etc.; Chevalier de la Légion d'Honneur. Paris: Félix Alcan. 1887.

This work, on the treatment of metritis, contains the lectures of Dr. Martineau, delivered at the clinic of gynecology and syphilography of the Hôpital de Lourcine during the course of 1886. The subject is treated of most comprehensively, and in a very readable style.

Gynecological Diagnosis; General Gynecological Therapeusis. By R. Chrobak, M.D., Professor of Gynecology at the University of Vienna. And Electricity in Gynecology and Obstetrics. By Egbert H. Grandin, M.D., Obstetric Surgeon to the New York Maternity Hospital. New York: William Wood & Co. 1887.

These two treatises comprise the fifth volume of the "Cyclopædia of Obstetrics and Gynecology," issued by William Wood & Co. as their annual "Library" for 1887. The first part deals with the methods of gynecological examinations, and with the instruments employed. The second part treats of minor gynecological operations, the use of tampons, of the curette, of local applications, and of pessaries. In the third part Dr. Grandin, the editor of the Cyclopædia, discusses the use and mode of application of electricity in gynecological and obstetrical practice. A chapter is devoted to electrolysis and to Apostoli's method of treating uterine fibroids. There are one hundred and sixty illustrations in the two treatises. This volume forms a most excellent introduction to the science and art of gynecology as it is developed in the succeeding volumes of the series.

Nationalitet en Natuurwetenschap. Door B. J. Stokvis. Haarlem: De Erven F. Bohn. 1887.

This is an address on "Nationality and Science," delivered at the opening of the First Netherland Congress of Naturalists and Physicians, held in 1887.

Sterility: Developmental Anomalies of the Uterus. By P. Müller, M.D., Professor of Obstetrics and Gynecology at the University of Berne. And The Menopause. By E. Börner, M.D., Professor of Obstetrics and Gynecology at the University of Gratz. With Fifty Fine Wood Engravings. Edited by Egbert H. Grandin, M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc. New York: William Wood & Co. 1887.

This book forms the eleventh volume of the "Cyclopædia of Obstetrics and Gynecology," appearing as Wood's Series for 1887. The first part, on sterility, deals with this condition as it occurs in man as well as in woman. The subject is treated of in a scientific spirit, and without the introduction of the questionable anecdotes for which many writers on this condition seem to have such a *penchant.* For this reason lay readers will probably vote the work stupid, but their loss is the true student's gain. The second part is an interesting essay on the congenital malformations of the uterus. In the third part Dr. Börner considers the menopause, and the symptoms and complications connected therewith. This book is, perhaps, the most interesting of the series to the general practitioner.

DISEASES OF THE OVARIES. By DR. R. OLSHAUSEN, Professor of Obstetrics and Gynecology at the University of Halle. With Thirty-six Fine Wood Engravings. Edited by EGBERT H. GRANDIN, M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc. New York: William Wood & Co. 1887.

IN this volume, of over four hundred pages, which is the eighth of the "Cyclopædia of Obstetrics and Gynecology" (Wood's Library for 1887), the question of ovarian disease is discussed ably by Dr. Olshausen. The first half of the book is taken up with a consideration of the diseases of these organs, while the latter half treats of the operations for the removal of sound and diseased ovaries. The seeker after information on ovariotomy is doubly blest in this Cyclopædia, for Kaltenbach and Hegar discuss the same subject at length in the latter part of volume sixth.

DISEASES OF THE TUBES, LIGAMENTS, PELVIC PERITONEUM, AND PELVIC CELLULAR TISSUE; EXTRA-UTERINE PREGNANCY. By L. BANDL, M.D., Professor of Obstetrics and Gynecology at the University of Prague. And DISEASES OF THE EXTERNAL FEMALE GENITALS; LACERATIONS OF THE PERINEUM. By P. ZWEIFEL, M.D., Professor of Obstetrics and Gynecology at the University of Erlangen. With One Chromo-lithograph Plate and Eighty-eight Fine Wood Engravings. Edited by EGBERT H. GRANDIN, M.D., Obstetric Surgeon to the New York Maternity Hospital; Instructor in Gynecology at the New York Polyclinic; Fellow of the Obstetrical Society, etc. New York: William Wood & Co. 1887.

THIS is the concluding volume of Wood's Library for 1887, "The Cyclopædia of Obstetrics and Gynecology." In this most excellent series we have the best works of the best German gynecologists, and, taken together, they make up a Cyclopædia of great value to the general practitioner and to the gynecologist as well. It contains the best thought of the most advanced of Continental specialists and teachers, and, owing to the judicious and painstaking editing of Dr. Grandin, the work is made for all practical purposes a genuine American one. The editor has added copious notes, wherever needed, by reason of some slight omission of the author or because of some statement at variance with the accepted teaching of American gynecologists. The illustrations are in the main very good, and the mechanical work on the book leaves nothing to be desired.

DE L'ÉLECTRICITÉ COMME AGENT THÉRAPEUTIQUE EN GYNÉCOLOGIE. Par le DOCTEUR PAUL F. MUNDÉ, Professeur de Gynécologie à la Polyclinique de New York et au Dartmouth College; Gynécologiste à l'Hôpital du Mont-Sinaï, etc. Traduit avec l'Autorisation de l'Auteur, et Annoté par le DOCTEUR P. MÉNIÈRE, Professeur libre de Gynécologie, Rédacteur en Chef de la *Gazette de Gynécologie*, etc. Paris: Octave Doin. 1888.

THIS is a French translation of Dr. Mundé's treatise on "Electricity as a Therapeutic Agent in Gynecology."

TEXT-BOOK OF THERAPEUTICS AND MATERIA MEDICA. Intended for the Use of Students and Practitioners. By ROBERT T. EDES, A.B., M.D., Fellow of the Massachusetts Medical Society, etc. Philadelphia: Lea Brothers & Co. 1887.

THIS is a practical work, well adapted for the use of those who have already some knowledge of the principles of materia medica and of experimental therapeutics, and who wish to review their work and to fix in their minds the essentials of the drug treatment of disease. The student preparing for examination, or the hospital interne, or recent graduate, will derive great benefit from a study of this book. The author has the gift of conciseness, and has well succeeded in his endeavor to present only the practical and really useful facts of therapeutics. He is wisely conservative in his views concerning the virtues of drugs, and, while not a nihilist in therapeutics, seeks to moderate the too enthusiastic notions of the curative effects of medicines, which works on therapeutics are too apt to excite.

A PRACTICAL TREATISE ON MATERIA MEDICA AND THERAPEUTICS. By ROBERTS BARTHOLOW, M.A., M.D., LL.D., Professor of Materia Medica, General Therapeutics, and Hygiene, in the Jefferson Medical College of Philadelphia, etc. New York: D. Appleton & Co. 1887.

A COMPARISON of this edition of Bartholow's deservedly popular treatise with the first edition of the same work, published just a decade ago, shows well the remarkable progress that has been made in therapeutics, or, more correctly speaking, in additions to the materia medica. The first edition contained less than five hundred and forty pages, while this has over eight hundred. Many new remedies, chiefly hypnotics, antiseptics, and antipyretics, have appeared since the first edition, and new uses have been discovered for many of the less recent drugs. It would be useless to review this book at any length, for it is a standard work, the excellencies of which are known to all. The only office of the reviewer is to chronicle the appearance of new editions as they succeed each other in rapid procession.

LES MÉTHODES ANTISEPTIQUES DE PANSEMENT, en Temps de Paix et en Temps de Guerre. Par le DR. JEAN HABART, Médecin Régimentaire de la Garde Royale Hongroise. Traduit de l'Allemand, avec l'Autorisation de l'Auteur, et Annoté par le DR. FREDERIC WEISS, Lauréat de la Faculté de Médecine de Nancy, Médecin Aide-major de 2e Classe de la Réserve. Paris: G. Steinheil. 1887.

THIS little book contains much valuable information on the methods most commonly employed in the antiseptic dressing of wounds, and on the best means of obtaining antisepsis in field hospitals and ambulances.

DIFFERENTIAL DIAGNOSIS: A Manual of the Comparative Semeiology of the more Important Diseases. By F. DE HAVILAND HALL, M.D., Assistant Physician to the Westminster Hospital, London. Third American Edition, thoroughly Revised and greatly Enlarged. Edited by FRANK WOODBURY, M.D., Professor of Therapeutics and Materia Medica, and of Clinical Medicine, in the Medico-Chirurgical College, etc. Philadelphia: D. G. Brinton. 1887.

THIS is a very useful book. It is of moderate size and well printed, easy to hold, and easy to read. The matter is arranged conveniently for reference, and, while not sacrificing clearness, the author and editor have been economical of words. Thus one turns to any disease and finds there a statement of all the prominent symptoms, without waste of time in weeding out the superfluous and the confusing from the important. The book is lacking, however, in one very convenient, if not essential, feature; its index is poor. It would have been easy to make a complete index, so that one could turn to it and find, without loss of time, a list of all the diseases in which any one symptom is a prominent feature. To a young practitioner such a semeiological index would have increased the practical worth of the book a hundredfold. However, the work is a very useful one as it is, and will be of great assistance to the recent graduate, and even older men may not infrequently find it serviceable in recalling to their minds some little, but important, point which had for the moment escaped them.

Reports of Societies.

NEW YORK ACADEMY OF MEDICINE.

Stated Meeting, January 19, 1888.

Abraham Jacobi, M.D., President, in the Chair.

The library of Dr. W. D. Schuyler, consisting of one hundred and seventy-six valuable volumes, the presentation of his widow, was accepted with thanks by the Academy.

Dr. A. Caillé read a paper on

A METHOD OF PROPHYLAXIS IN DIPHTHERIA.

There are, the author said, children subject each year to attacks of diphtheria, usually in the fall and spring. According to his experience such attacks recur usually in October, November, March, and April. May not these persons harbor the microbes or factors essential to the development of diphtheria in an unhealthy nasal and oral cavity? He had sought to establish the correctness or fallacy of this view of auto-infection by experiments upon eight subjects, who, prior to 1885, had had two or more attacks of diphtheria. The parents carried out the following instructions: 1. All carious teeth to be filled or extracted, the teeth to be examined by a dentist from time to time. 2. The mouth to be thoroughly rinsed three times a day, after each meal, with one of the following solutions; namely, a three per cent. solution of potassium chlorate in water, a five per cent. solution of liquor sodæ chlorinatæ, or a saturated solution of borax in water, a portion of the liquid to be drawn into the nose. In addition to these eight cases there were two infants, each aged about one year, who had never had diphtheria, who were treated by regularly dropping some of a solution of borax into the nose, especially when nasal catarrh was present. As a result, up to December, 1887, patients one, three, four, six, and eight had had several attacks of acute pharyngitis and amygdalitis, characterized by only a moderate amount of swelling of the tonsils and moderate fever, but none of these or of the other patients had true diphtheria. Patients one, two, and three, members of the same family, did not contract diphtheria, although the mother and a nurse had the disease.

While these observations were too limited to base upon them definite conclusions regarding the value of such prophylaxis, he thought we were justified in the belief that if the nasal and oral cavities could be kept clean by a mild antiseptic solution, the frequency of diphtheritic inflammation would be markedly reduced. If we admit our ignorance of the true nature and significance of so-called diphtheria, we will have to acknowledge the difficulty of differentiating clinically between the contagious and the non-contagious acute affections of the nasal and faucial mucous membranes, and we are thus led to look with suspicion upon all such changes, and to apply prophylactic measures. In the present state of our knowledge, prophylactic measures will prove of more value to the community than methods of treatment of diphtheria after it is once developed.

A few words about prophylactic measures.

We have, in the first place, general preventive measures, such as hygienic methods, relating to clothing, feeding, isolation in homes and hospitals, etc. Second, there are the prophylactic methods pertaining to the family, and directed to the individual. While public sanitation should be carried out strenuously, yet the author was convinced that the utmost importance should be attached to personal and individual preventive measures. Yet very little information on this point could be obtained in the vast amount of literature on diphtheria.

Résumé.—In a city with densely populated districts, the supervision of plumbing, the erection of air-shafts in tenements, were useful supplementary sanitary measures to individual prophylaxis against diphtheria, and physicians should instruct the people in such matters as often as opportunity presents. Overheating of school-rooms and of dwellings should be most emphatically denounced as dangerous. Isolation of the sick should be explained and insisted upon. The management of isolation-houses for the poor should be such as to readily gain their confidence. Enlarged tonsils should be reduced. Carious teeth should be removed or filled promptly. The fee of the poor therefor should be small, or nothing. Parents should inspect their children's mouths and throats each day before they go to school. Children should learn to gargle at an early age. Children suffering from simple sore throat, apparently, or from follicular amygdalitis, should not attend school until well. Kissing upon the lips should be forbidden. Children old enough to gargle should be taught to do so after each meal, with a weak solution of an antiseptic chemical, and in young children a few drops should be dropped into the nostrils.

Recognizing that it is impossible to lay bare and control all sources of diphtheritic infection, it will be more practical to teach the individual to protect himself by selecting his surroundings and striving to keep healthy those parts which are found by experience to be generally affected by diphtheria.

Dr. George T. Harrison had had such painful experience with regard to curative treatment of diphtheria that he had listened with much interest to what the author had to say regarding preventive measures. He had learned some new points. Dr. Caillé had done well in calling attention to the paper once written by the President, and published in The Medical Record, concerning amygdalitis.

Dr. Fruitnight said that often the first case of diphtheria in a family died before the physician was called in, and thus the parents learned, thereafter, to inspect the mouth and throat of their children frequently. It would be natural to suppose that a healthy mucous membrane in the nasal and faucial cavities would militate against the development of diphtheritic germs, and when the disease existed in a family it would be well for those not yet infected to use a disinfecting gargle.

Dr. Simon Baruch thought daily insufflation of a cold solution into the nose would be a dangerous procedure.

Dr. Pooley said that all medication of the nose should be lukewarm at least. With a post-nasal syringe and a warm solution almost any person could safely wash the nose.

Dr. Seibert fully coincided with the speaker of the evening. If he understood him aright, he wanted to keep the mucous membrane of the nose, mouth, and throat clean. He would add thereto the necessity for keeping the stomach in order, for with a disordered stomach the mouth, and particularly the tongue, could not be kept clean. No candy should be sold near a public school, for he had seen repeatedly attacks of diphtheria in his own children due to a spoiled stomach which began in the eating of candy at school.

The President said it was a well-recognized fact that the worst forms of septic disease are not infrequently connected with immense glandular swellings, and, indeed, the severity of many cases is manifested in the degree to which the neighboring lymphatics are affected. Everyone, he believed, would give a grave prognosis in diphtheria when there is much œdematous swelling and enlargement of the lymphatics near the angle of the jaw. He felt sure that the diphtheritic poison could remain in the mucous membrane and neighboring lymphatic bodies. As long as the mouth and pharynx are healthy, particularly the mucous membrane, diphtheria will not show itself so easily.

RENEWED ATTACKS OF DIPHTHERIA

also arise by infection from the carpets, curtains, and furniture of the room in which the sick have lain. Hence the importance of having at least two rooms, and of removing the patient from the one to the other every two or three days to admit at least of thorough ventilation and cleansing, if not of disinfection. In some cases he had found it necessary to have the children removed to another house before they would finally recover.

Dr. L. E. Holt had the impression that enlarged tonsils favor the development of diphtheria and make the disease more severe when it occurs. He inquired of the speakers whether their experience supported that view.

The President said his experience accorded therewith.

Dr. Joseph E. Winters prevented the spread of diphtheria in families, in which some member was affected, by isolation, disinfection, and enforcing hygienic rules on the other members; but, in addition to these general measures, he gives to the well children full doses of the tincture of chloride of iron three times a day, and tonic doses of quinine; also small purgative doses of calomel.

THE INDUCTION OF PREMATURE LABOR IN AMAUROSIS AND AMBLYOPIA IN ALBUMINURIA FROM PREGNANCY.

Dr. T. H. Pooley read a paper with the above title (*vide* p. 93).

Dr. Loring opened the discussion with remarks insisting upon the importance of an ophthalmoscopic examination during pregnancy. It is easy to determine with the ophthalmoscope the presence of the albuminuria retinitis. Disturbance of vision may occur from uterine disturbances in the non-pregnant. A girl eighteen years of age accidentally discovered that she was losing sight in one eye. She sufferred from menstrual disturbance. An oculist examined her eyes and said there was atrophy of one optic nerve. Every effort was made to induce return of the menstrual flow, which succeeded, but vision in that eye was lost. About a year afterward she consulted Dr. Loring, with failing vision in the other eye, and he found neuro-retinitis. Menstruation was again irregular. She married, and vision became better. Again, after nursing a child about three months vision began to fail. According to advice, she weaned the child, leeches were applied to the temple, the menses were brought on, and vision returned. Kidney disease could not be detected. She was not hysterical.

Dr. Murray thought the conclusions reached by the author were not justified even by the facts presented. The quotations of Dr. Loring showed that neuro-retinitis is present in a large percentage of pregnant women; yet the proportion of pregnant women who have eclampsia accompanying albuminuria is small, and a small proportion of these again have serious disturbance of vision. The inference is that the revelations of the ophthalmoscope when used in all cases of pregnancy give rise to needless anxiety to physician and patient. His own experience also confirmed the view that the general use of the ophthalmoscope in pregnancy is needless.

Drs. Baruch, Fruitnight, Harrison, and The President also made some remarks, and, in closing the discussion, Dr. Pooley said that the argument in his paper was in behalf of saving sight in these cases, and he thought it was evident from the facts presented that when grave organic disease of the eye exists during the albuminuria of pregnancy the chances for vision are better when pregnancy is terminated prematurely.

Pilocarpin in Bright's Disease.—Dr. Heitler stated the other day that he had never seen any good result follow the use of pilocarpin in renal disease after ascites had once set in. On further questioning him afterward he admitted that it produced its physiological effects of increased perspiration and urination, but believed these to be purely temporary and to have no beneficial result, whereas the depression consequent upon the use of the drug was not seldom alarming. He used it subcutaneously in doses of gr. $\frac{1}{6}$ administered every other day.—*Vienna Correspondence Birmingham Medical Review.*

NEW YORK NEUROLOGICAL SOCIETY.

Meeting held December 3, 1887.

The President, Dr. C. L. Dana, in the Chair.

Dr. J. C. Shaw reported

A CASE OF CEREBRAL TUMOR.

The patient was a male, aged forty-one, a jeweller by trade, temperate, and previous history good; no syphilis.

In 1879 the patient had an attack of rigidity in the night, followed by a deep sleep. March 19, 1882, he had an epileptic attack, the convulsion commencing in the left side of the face and extending to the neck, so that the head was twisted to the left side, and the eyes were turned upward. Thus far the patient was conscious, and had raised the left arm to strike upon his bench to attract help, when his arm was seized with the spasm, and he knew nothing further. The attack was followed by sleep. He had had as many as four such seizures in a week. In one attack observed by the speaker, the left side of the face and the left arm had been principally affected. There had been no loss of consciousness in this attack.

The convulsions were preceded by a peculiar, painful sensation in the roof of the mouth and teeth. There was more or less numbness of the left side, the tactile sensibility of which was diminished. Two points were recognized upon the left hand only when 4 c.c. distant, while upon the right hand two points were recognized when 1 c.c. distant.

January, 1886, headache commenced to be complained of, also nausea. Choked disk was now found. August, 1886, vision was almost lost. Headache and nausea continued and mental cloudiness was apparent. February 4, 1887, the patient would fall to the right side, there was paresis of the left arm and leg, and the patient could not tell when lightly touched. He was now weak, thin, and confined to bed. March, 1887, urine and fæces were passed involuntarily. In May a bed-sore appeared. June 21st, the patient suddenly became comatose, with puffing respiration, chiefly abdominal. After thirty-six hours he recovered from this, but July 1st died of exhaustion, extremely emaciated. The skull was found very thin, the veins of the meninges prominent. On lifting the brain the posterior fossa was found to contain fluid, the origin of which did not appear. The left hemisphere showed no gross lesion. In the right hemisphere the dura was adherent throughout a localized patch, dark-brown in color, and occupying the lower part of the motor zone, beneath which softening appeared. The basal ganglia were free.

The pain in the teeth, complained of at the commencement of the spasm, had suggested a reflex from the dura to the fifth nerve. The reader considered it not illogical to conclude that the numbness, too, was to be explained by the irradiation of this reflex to other portions of the sensory tract. The apoplectiform seizure was probably due to hemorrhage into the softened mass. The opinion of the members was requested upon this point.

Dr. Dana inquired in regard to the character of the growth.

Dr. Shaw replied that section had not yet been made, but he considered the growth a glioma.

Dr. Dana found the growth occupying only the lower part of the præcentral convolution and not involving the parietal lobe.

Dr. Seguin remarked that as the pia was *in situ*, exact location was difficult; but that, according to his judgment, the lower part of the præcentral and the posterior extremity of the second frontal and of the third frontal convolutions were involved. The fact that Dr. Shaw had observed no laryngeal symptoms was interesting.

Dr. Birdsall, referring to the sensory symptoms, remarked that the tumor was not simply a cortical lesion, it extended inward, and more central tracts had probably been involved.

Dr. Starr added that sensory symptoms accompanied motor impairment where the parietal lobe was invaded. As a rule, where cortical motor lesions were without sensory disturbance, the location of such lesions was anterior to the fissure of Rolando. Where sensory disturbances were also found, it was posterior to that fissure. In this case, however, it was not impossible that congestion posterior to the fissure would explain the symptoms.

Dr. Seguin remarked that the subject of sensory disturbance in connection with cerebral tumors was most interesting and important. In his own experience a slight diminution of sensibility had accompanied lesions of the motor-centres, even when confined to the cortex. Nothnagel, at the Congress for Internal Medicine in Germany, had referred to slight tactile anæsthesia in a large number of cases of tumor or lesion of the motor-cortical centres. These were, however, without loss of the muscular sense. It was conceded that the muscular sense was located in the parietal lobe. In a case of Dr. Weir's, with sarcoma involving the fasciculus for the face and hand, there was distinct anæsthesia of the face and hand, but no loss of the muscle-sense, as tested by passive motion and weights.

Dr. Starr presented

A CASE OF COMBINED SCLEROSIS

in connection with Dr. Putnam's paper. The patient had been under his care for nine or ten months. He was sixty-two years of age, of good family history, and no syphilis. Eight or nine years ago he had commenced to complain of dull, aching pain in the sacrum and down the legs. He had had no lightning pains, but a progressive difficulty in locomotion, until he was now markedly ataxic. There was increased tendon-reflex at the knee. The case differed from that of ordinary locomotor ataxia in the absence of lightning pains and the absence of the loss of the tendon-reflex. There had been slight enuresis, but the urine was now retained. The pupils were contracted, but were not of the Argyll-Robinson type. They reacted both to light and to accommodation, but sluggishly. The tremor of the muscles of the face referred to by Gowers was present. It was a light tremor, like that of paretic dementia.

The Chairman then introduced Dr. Putnam, of Boston, the President of the American Neurological Association.

Dr. Putnam presented a

REPORT OF THE EXAMINATION OF THE SPINAL CORD IN A CASE OF COMBINED SCLEROSIS.

The patient was a female, fifty-eight years of age, whose father had died at eighty, and mother at eighty-three years. The patient had been divorced from a first husband on account of his immoral conduct. Her second husband was also dissolute. When twenty-eight or twenty-nine years of age the patient's hair had fallen out. There had been no eruption noticed. The patient had used stimulants freely, but never in excess. Beginning in 1880, she had suffered with diarrhœa. Brown discoloration of the skin of the left arm and neck was then noticed. Subsequently the skin of the abdomen became a deep chocolate color, and the pigment of the nipples and axillæ increased and deepened. When first seen by the reader her face was as dark as that of an Indian, and roughened with scales and exudation. In 1883 she was treated for anæmia and dyspepsia, the nerve-affection not having appeared until two or three years ago. The first nerve-symptom was numbness in the fingers. In November, 1886, she had lost power in the limbs, so that her gait was unsteady. She had difficulty also in the use of her hands, and was said to have fainted at one time with her teeth clinched. Her motor inability consisted in inco-ordination rather than paralysis. She had no lightning pains, but closing the eyes increased the inco-ordination, failing to reach the spot aimed at with her hands within four inches. On account of her mental apathy her sensory condition could not be made out. Her answers to questions were not correct. She had a ravenous appetite, and the diarrhœa continued. Taste had been impaired for several years. During the following six months the legs became completely paralyzed, and the patient died, April 8, 1887, six months from the onset of the ataxia and the paraplegia. The symptoms of ataxic dementia were prominent in the ravenous appetite and disordered taste, leaving the diagnosis, perhaps, open to question, as examination of the brain was not permitted. Spitzka has found degeneration of the lateral tracts in dementia, but coincident degeneration of the pyramidal tracts was not present in these cases.

The post-mortem examination showed in the lower ileum several ulcers, apparently tubercular in origin. In the cord there was softening of all the tissues at the level of the fourth dorsal nerve. There was extreme whiteness and no trace of vascularity in this part. The cord was examined from the region of the first lumbar to that of the second cervical vertebra. The posterior columns, through their whole extent, showed a condition like that of a primary sclerosis. At the level of the twelfth dorsal vertebra there were two sclerotic areas, one external to the column of Goll, in the column of Burdach. The lateral columns appeared as described by Spitzka in his two cases of primary dementia. The septa between the nerve-spaces were broken down, so that holes appeared in the sections, with fragments of myeline and granular cells. These changes were confined to the lateral pyramidal columns, up to the middle cervical region, where the direct cerebellar tract of both sides took on the same appearance, and the diseased lateral area became less.

It was noted that the softened spot might have been due to anæmia or to myelitis. It was against the latter theory that the vessels were here shrunken, and there was no transudation of white globules to be seen. The degenerations were not in direct relation with this softened tract. The posterior nerve-roots were healthy. The anterior nerve-roots were affected with different degrees of inflammation.

The reader referred to Strümpell's and Gowers' classifications, also the general question of primary systematic sclerosis of the spinal cord.

Dr. Starr considered that the exhibition of specimens placed the diagnosis of combined sclerosis in this case beyond doubt, and, inasmuch as the case had presented symptoms not recognized as belonging to this condition, the paper was one of unusual service by enlarging our clinical picture of the disease. The exact pathological difference between the condition of vacuolization in the lateral columns, and that of the ordinary sclerosis of degeneration was a matter of interest. In these specimens the lateral columns were vacuolized, and in the posterior columns the connective tissue was increased; yet both processes were called sclerotic when they probably should be differently classed.

Dr. Starr presented sections, one from the original case of Friedreich's disease, and one from a case of ordinary sclerosis, each presenting the distinctions referred to in Dr. Putnam's paper.

Dr. Seguin considered the change in the lateral columns in Dr. Putnam's specimens in front of the region of the crossed fasciculi. In one section it was even in front of the transverse diameter. The same violation of the limits of the pyramidal fasciculi had been observed in a case of his own. In this case the paresis predominated, and the patellar and solar reflexes were exaggerated. In another case, referred to him by Dr. Hunn, of Albany, ataxia and posterior-column symptoms predominated, and there was no tendon-reflex. There was anæsthesia, fulgurating pains, and ataxia of the legs and hands, with gradual paralysis. One or the other lesion would predominate in such cases, producing variety in the symptoms. Errors in diagnosis were easy.

Nodular or insular sclerosis, if distributed in the posterior and lateral columns, would give the clinical picture of combined sclerosis. Charcot had even lectured upon a case as spastic paralysis, to find, upon autopsy, nodular or insular sclerosis. Diagnosis should be guarded.

Dr. Birdsall, referring to the specimens under the microscope, found in the posterior columns ordinary sclerosis, and in the lateral columns separation and swollen myeline sheaths, the axis-cylinders being in position in some places, and in others simply spaces between the neuroglia-elements, as though the myeline and axis-cylinders had dropped out. In judging of this condition, one had to remember the different normal structure of the two regions, the finer fibres and finer neuroglia-elements in the posterior columns. With Dr. Seguin, he found the degenerated area forward of the transverse line of the central canal, and extending even half-way up the anterior horn, taking in the region described by Gowers as the ascending cerebral tract, obtained by physiological and embryological data. The speaker inquired whether there had been any chance for post-mortem softening of the cord which would explain the vacuolization.

Dr. Putnam thought there had not been any such chance, as the specimen had been dropped into Müller's fluid within one hour after removal. The nature of the change in the lateral columns showed that it had been rapid, from the fragments of granular myeline scattered about, and it was suggested that the spaces might have been caused by albuminous fluid which had been poured out and coagulated. The section showing the degenerated area anterior to the transverse diameter had been taken from the upper cervical region, where the direct cerebellar tract carries the area forward.

Of the three varieties of mixed sclerosis, the spasmodic was represented by a case of Strümpell, the ataxic by Dr. Starr's case, and the paralytic by a case of Strümpell and by his own.

Dr. Dana had had occasion to collect and study the cases of combined sclerosis reported, with autopsy, adding two new ones. The subject was still far from being settled, but continued experience led him to much such a classification as Strümpell's. Pathologically, he thought the cases of combined sclerosis were, first, cases of diffuse dorsal myelitis, with the lateral and posterior scleroses more or less secondary. They formed, usually, the spastic type. He was inclined to think that Dr. Putnam's case might go in this category. Second, cases of atypical tabes, with extension of the sclerosis in the lateral columns. These formed the ataxic type. The speaker believed that Dr. Starr's case was one of atypical tabes. He had seen several such cases, and had found, after a time, that the spastic symptoms disappeared, and the patients were simply locomotor ataxics. The posterior lesion was at first high up, and perhaps with some extension laterally. The third class of cases was that of primary tri-fascicular sclerosis. These cases were very rare.

Dr. Putnam stated that as the degeneration was found both above and below the softened area, it could not have been secondary to it; also the involvement of the whole lateral tract would have required a focal lesion above, which was not obtained.

TREPHINING FOR EPILEPSY.

Dr. Dana presented the calvarium and brain of a young woman, trephined over the site of an old fracture for epilepsy and maniacal attacks. The operation had been done by Dr. Robert Abbe, with all antiseptic precautions, yet persistent high temperature followed, with death on the tenth day.

A small subdural cyst was evacuated at the time of the operation. The autopsy showed old leptomeningitis, with recent meningitis, and acute red softening under the injured part. The question of the safety of trephining was brought up.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, December 28, 1887.

William P. Northrup, M.D., Vice-President, in the Chair.

Dr. John J. Griffiths presented two specimens, which illustrated

CEREBRO-SPINAL MENINGITIS WITH PUS AND FIBRIN IN THE CEREBRAL VENTRICLES.

Case I.—Theresa C——, aged five months, was born in the New York Foundling Asylum, and had been out to a wet nurse. On November 8, 1887, she was brought to the Out-door Department, with a history of constipation and repeated convulsions. She was pale, restless, and had a moderate cough.

She was returned to the house with a diagnosis of meningitis.

Dr. Hopkins, the House Physician, furnishes a history of subsequent repeated convulsions, obstinate constipation, trismus, and unilateral convulsions. No opisthotonos. The symptoms continued four days, the patient dying on November 12th.

Autopsy by Dr. W. P. Northrup: The body was poorly nourished; hair worn off the occiput from constant rolling of the head; no eruption.

Brain.—A thick layer of greenish pus and fibrin was spread over the convexity and base, enveloping it everywhere, and extending down and enveloping the cord. The lateral ventricles were dilated to twice their normal size, and contained an abundant exudate of pus and fibrin, which also extended into the third and fourth ventricles. The central canal of the cord was not dilated. The floors and walls of the ventricles were slightly reddened, vascular, and softened.

Case II.—Josephine S——, aged four months and five days, was brought to the Out-door Department of the same institution on December 1, 1887, with a history of convulsions, opisthotonos, constipation, and left convergent strabismus. She manifested the same symptoms for the following sixteen days, and died, December 17th.

Autopsy by Dr. W. P. Northrup forty-eight hours after death: The body was extremely emaciated; no eruption.

Brain.—On opening the skull the convolutions were seen to be distinctly flattened and dry. There was no exudate upon the vertex, lateral surfaces, or base. The ventricles were dilated to three or four times their normal size, and within them were thick masses of pus and fibrin exudate, extending from the lateral into the third and fourth ventricles. The cortex was not softened; neither was the corpus callosum.

There was moderate softening of the walls of the ventricles, especially the floors.

At the level of the floor of the fourth ventricle, posteriorly, the inflammatory process seemed to have communicated with an area of cerebellar meningitis, which, in turn, extended down the cord as an ordinary spinal meningitis.

The area of cerebellar meningitis was about the size of a silver half-dollar. The central canal of the cord was not dilated.

The pus and fibrin exudate was thus found within the ventricles, upon a limited area of the cerebellum, and investing the medulla and cord.

In reviewing these cases it will be seen that both children were between four and five months old; both were wet-nursed; both females; and both gave symptoms of constipation and convulsions.

The point of special interest is thought to reside in the extensive pus and fibrin exudate in the ventricles.

In Case I. the exudate in the ventricles was associated with extensive exudate over the entire convexity of the brain and about the cord.

In Case II. the exudate in the ventricles was associated with a spinal meningitis, the two forming a continuity of lesions through the thin wall at the floor of the fourth ventricle at its lowest extremity (foramen of Magendie).

In neither case was there any dilatation of the central canal of the cord.

Dr. Northrup remarked that these two brains were the first cases in which he had seen the ventricles involved. He had seen them contain serum in moderate amount, but without dilatation. In tubercular meningitis the ependyma is frequently involved, small, discrete tubercles being easily demonstrated upon it, the ventricles being at the same time dilated and containing serum. This condition could not be called rare.

In cerebro-spinal meningitis, according to the literature of the subject, the ventricles may be dilated and contain sero-pus. This he regarded as rare.

In a moderate search through the literature he had not met with the description of any case in which the lesion had avoided altogether the convexity of the cerebrum and cerebellum, and expended itself in the ventricles of the brain and upon the meninges of the cord.

The sero-pus of the ventricles seemed to have its origin in the vessels of the velum interpositum, which are continuous with those of the pia mater.

Dr. A. Brothers presented a specimen of

CLEFT TONGUE,

with the following history: Amelia H——, aged one month, was referred to him by Dr. C. E. Denhard. At birth the midwife noticed a cleft in the palate, which has interfered with the proper feeding of the infant. Nursing was impossible, and milk poured into the child's mouth was returned through the nostrils. Although well-developed at birth it has steadily pined away, and when he saw it, on December 27th, it was evidently dying from marasmus. During the past few weeks it had suffered from diarrhœa, for which no physician was consulted. There were two older children in the family, but they were normally developed.

The specimens showed a fissure in the soft palate extending up to the hard palate, and a cleft one-eighth of an inch deep at the tip of the tongue. The lungs were œdematous, and showed hypostatic congestion at the bases. The heart was normal. The liver was very much congested. The kidneys (only one was removed) showed a small cavity, evidently a cyst.

There was a marked irregularity in the alveolar portion of the inferior maxilla, as though the gums were deficient.

The case was interesting on account of the lack of complete closure of the apex of the tongue, which he thought was quite rare.

Fissure of the palate was of interest because the child was likely to die from lack of nutrition. Had this child been properly fed from the beginning, attention having been paid to getting the milk well down into the œsophagus, so that it could not return through the nose, its life might probably have been saved.

Dr. Lewis Hall Sayre presented

THE HEAD OF A FEMUR REMOVED BY EXSECTION

at St. Vincent's Hospital. H. M. McK——, thirty years of age, a resident of Illinois, remarkably active and athletic, while being initiated in a secret society in May, 1883, was pressed upon by several men while he was bent over, causing very severe pain in the lumbar and dorsal regions, and making him fall to the floor in great agony. He recovered in a short time, and went through with the ceremony. On the next morning he felt a sensation of itching along the left side of the back, and two weeks later had pain in the right groin, and could not walk without the aid of a cane or crutch, because he was unable to bear any weight upon the right leg.

The case was diagnosticated as rheumatism, and the patient resided in Colorado and Mexico two years and four months, where he underwent treatment, but without benefit.

During this time he was always compelled to raise himself on his hands whenever, from any cause, the street-cars jolted. He then began to notice that he was getting out of shape, and went to a gymnasium for the purpose of correcting that tendency. While swinging suspended by his hands he always felt better, but whenever he came down upon his heels he suffered great pain, and, therefore, he always lowered himself very carefully. In the meantime his physicians insisted that his trouble was rheumatism.

Up to this time no knuckle had been detected in his back, although he was aware that he was

TWISTING SIDEWAYS TO THE RIGHT.

While riding on horseback he had to raise himself from the saddle by his hands whenever the horse jumped over any obstacle. In 1886 he had a brace applied, but was unable to wear it. A plaster-of-Paris jacket was also unsuccessfully applied, although it gave him some comfort. He then had another brace applied, but was unable to wear it, and finally came to Dr. Sayre for a plaster jacket, because the first one put on in Chicago by Dr. Gunn had afforded him some relief. That was on April 21, 1887, and he was then walking with a pair of crutches, and his right leg was flexed and abducted. Careful examination revealed morbus coxarius of the right side, in addition to the spondylitis of the lumbar vertebræ, which had become quite prominent. Partial suspension gave him instant and complete relief from pain. Two days afterward a "plaster-of-Paris jacket" was applied which, he said, gave him more comfort than anything he had worn. But when his back had been made easy, he felt the pain in his hip, which he had not thought of before. A weight and pulley were then applied to the limb, and the pain in his hip was relieved. A short hip-splint was then adjusted during the day, and he felt so comfortable that he left for his home in Texas, and was able to attend to his business, which required him to travel many thousands of miles.

He returned a few weeks ago, with his back nearly well, but his hip was worse. He had worn the short splint only one month. He had occasionally used extension at night; but, without the splint during the day, the disease had progressed until exsection was indicated, and the operation was performed, December 27th.

One month ago the patient's urine contained large quantities of albumen and pus, but they disappeared. The right limb was adducted, flexed at an acute angle with the thigh, and everted. There was intense pain on pressure of the head of the femur into the acetabulum. The head of the bone contained an abscess. The acetabulum was extensively carious.

Before the operation a peculiar clicking noise could be produced in the joint by manipulation, and it was found that the acetabulum contained a loose piece of cartilage that articulated with a corresponding eburnated surface upon the head of the bone, and gave rise to the peculiar sound.

Dr. Brothers asked if it was common for spondylitis and hip-joint disease to occur at the same time in one patient.

Dr. Sayre said that it was not infrequent. He had seen several cases.

The Society then went into executive session.

The types can sometimes make sad havoc with names, but rarely is the transformation so complete as in the case of Dr. Thomas H. Mays. The item started out as follows: "The prescription of thenic recommended by Dr. Thos. H. Mays for hypodermic uses;" it comes round to us now as "The prescription of thenic recommended by Dr. East, of Mayo."

Correspondence.

INCREASED PENSIONS FOR LOSS OF HEARING.

To the Editor of The Medical Record.

Sir : My attention has been directed by Captain A. G. P. Brown, acting in the interests of a large number of surviving soldiers, sailors, and marines who are suffering from the disability of deafness, to the proposed bill to be introduced this winter in the Fiftieth Congress, giving the class he represents increased pensions. The men who acquired aural disease with deafness in the line of duty have been greatly neglected, and I write this with the hope of enlisting the interest of medical men, especially those who served as medical officers themselves, in this meritorious measure ; believing that, if Congress and the President can feel assured that unjust claims can be detected, the bill will not be long delayed in its passage. Of course, deafness from natural causes among the survivors of the War of the Rebellion, of similar origin to that of persons of the same age and social condition who were not in the service, is common and must be excluded by pension-examiners ; but many soldiers came home from the field with partial loss of hearing, and managed to get on very well until their defect increased from some cause ; it may have been that one ear only was at first affected ; in this way their disability was greatly increased. There is undoubtedly a large class of men disabled in this manner worthy of pension.

Soldiers were not generally given to anticipating aid of this kind during the progress of the war, when most of them were young and strong ; but now, after the lapse of twenty-five years, existence in the decline of life requires a more severe struggle, and defects are felt which were never before taken into count ; indeed, many have been disinclined to apply for Government aid, though fairly entitled to pensions, so long as they could earn a livelihood.

The causes of deafness among men who served in the war may be included in three classes, namely : Shot-wounds involving the ear, rupture of the drumhead by explosives and injury of the inner ear by loud sounds, and exposure.

Shot-wounds involving the ear are not obscure in their nature, and were easily recognized. Injury from concussion of great guns and small arms is more difficult of recognition, especially after the lapse of many years, and claims should be fortified by evidence of exposure to injury as well as by special examination at the time of application. I have found these cases to be quite difficult. The existence of deafness from aural disease due to exposure is no more difficult of recognition than disability from diarrhœa, rheumatism, bronchitis, and the like.

Injury of the inner ear, if long time has elapsed, is difficult of recognition, and a decision must depend very much upon evidence as to the applicant's exposure. It has always seemed to the writer that exposure of the drumhead to the long-continued shock of musketry fire was injurious, though no deafness was ever traced to this cause while in the field. The following case, referred to me by Medical Director Delevan Bloodgood, U.S.N., however, seems to confirm the above conjecture. For its history I am indebted to Passed Assistant Surgeon Frank Anderson, U.S.N., U. S. Steamship Richmond.

David C——, ordinary seaman, twenty-three years of age, on October 27, 1887, was engaged in firing at a target with a Gatling gun in the bow of ship's cutter. He stood about two feet from the muzzle of the gun, passing ammunition, and to leeward of it, his back toward the bow, the left ear turned to the piece, during the firing of a thousand rounds of cartridges. The firing occupied about fifteen minutes. The discharges were in volleys of two hundred each, there being about two minutes' interval between each volley. Patient became so deaf, after about four hundred rounds had been fired, that he could no longer hear the orders given by the man feeding the gun. He therefore turned about while passing the rest of the ammunition so as to bring the right ear, which seemed less affected, toward the muzzle of the piece, turning half round when reaching for cartridges. There was a "stinging-pain" in and about the ears, extending through the head, especially the forehead. On returning aboard ship, about fifteen minutes afterward, he found that the deafness was increasing, and in about a quarter of an hour it was total. The head pained for some two weeks, and there was vertigo ; the pain behind the ears and sensitiveness to touch, especially on the left side, still continues. Tinnitus began soon after injury.

The left mastoid was blistered while on ship, where he remained three weeks after the injury. At first he was very nervous and could not sleep well on account of the noise and distress in ears and head, though he felt very drowsy. He is now in the Naval Hospital, where the left mastoid has been blistered three times and rubbed with oleate of mercury, and he is under a moderate course of iodide of potassium. The patient is of full medium size and has been in good health, though he never considered himself very strong. There is no history of any constitutional disease, and he says his hearing has always been very good. When examined by the writer (January 18, 1888), he did stagger, but occasionally felt a sensation, lasting a few moments, as if something was turning around in his head. He has lately complained of slight weakness of the left ear, but this is not marked. He is much run down and mentally depressed.

Examination of ears.—Left ear : The drumhead shows trophic changes ; at the umbo and posterior segment, radiating fibres are exposed to view. Short process very prominent. Stapes and long process of incus are plainly visible through the drumhead. There has been very decided chronic catarrhal otitis media. The entire peri-auricular region is tender to touch, though no other part of the head is. *Right ear :* Some symptoms of recent chronic catarrh are present. The drumhead is less trophic than the left. The cone of light is high up, above the umbo. Malleus plexus and tissues about the anterior superior quadrant are very decidedly injected.

Hearing.—At the sham battle which took place at Newport, after his injury, he was on deck of the Richmond and saw the action, but could hear no sound, not even the guns of his own ship, though he felt the deck tremble. The deafness is absolute ; cannot hear any impression of sound. Large vibrating tuning-fork on teeth or any part of skull not heard. Does not hear shouting or screaming into the ear through a conical conversation-tube. Patient does not hear his own voice, but speaks with very good modulation.

The importance of facing the piece in firing is shown by the result of neglecting such a precaution in this case, where the ear was presented to the muzzle—the effect of impact being greater owing to the direction of the wind. Nor were the ears protected by cotton-wool in the external auditory canals, which in this case were large. It may be remarked that the regularity and frequency of the impacts of intense sound upon the drumhead were sufficient to produce neuritis of the auditory nerve, though the drumhead was probably not ruptured. The intense vibrations of the barrels of the Gatling gun, when rapidly fired, must be very distressing to hear, even at some distance to the rear. They seem to vibrate much in the same manner as a tuning-fork.

Samuel Sexton, M.D.

12 West Thirty-fifth Street, New York.

The Hospital Saturday and Sunday Collection had reached at last report the sum of $45,000.

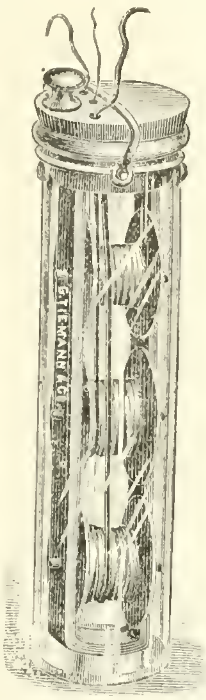
New Instruments.

A NEW ANTISEPTIC LIGATURE REEL.

By H. B. WARE, M.D.,

SCRANTON, PA.

There have been many attempts made to construct a bottle that would contain ligatures of gut and silk antiseptically, and at the same time be light and convenient to transport. But nearly all have soon been forgotten, owing to the fact that they were not antiseptic, or were so complicated that too much time was used in adjusting them.



The accompanying cut represents a bottle which does away with these faults. It is a glass bottle 3½ inches in length and ¾ of an inch in diameter, having a soft rubber stopper through which are three minute perforations. By pressing the stopper firmly into the bottle and pulling over the cap, no fluid can escape at all, and yet the ligatures can be freely drawn through. Attached to the stopper is the frame, which is entirely of hard rubber. The pins which hold the reels and the reels themselves are all hard rubber, so any antiseptic fluid may be used without in any way acting on them. A glance at the cut will show how easily and simply it is adjusted. In a minute's time a reel can be wound full of catgut or silk, and be made ready for use. Each reel holds about forty feet of No. 3 gut. The ligatures are passed through the stopper with an instrument which accompanies the bottle, or with an ordinary eyed probe.

A knot made by two strands of gut tied together will easily pass through the stopper. Thus the ligature bottle is always ready for use.

I recommend the Ligature Reel to the profession for its perfect antiseptic properties, simplicity of construction, and easy adjustment and cheapness.

Hallux Rigidus.—The symptoms of this condition, according to Dr. Cotterill, are more or less inability to dorsiflex the toe, accompanied by pain, in the early stage felt on the dorsal aspect, and later in the course of the disease in the plantar region. The author believes: 1. Hallux rigidus proper is due to the invariable combination of flat-foot and boot pressure. 2. That while no amount of flat-foot alone will cause it, a slight amount of flat-foot in combination with boot confinement is sufficient to bring it about. 3. That it exists, to a *certain extent*, in almost all cases of flat-foot occurring in persons wearing ordinary European boots. 4. Flat-foot occurring in barefooted nations, or in those who wear sabots or other such boots as provide for ample dorsiflexion of the great toe, does not cause it. 5. That the connection between it and flat-foot has been frequently denied or overlooked owing to the imperfect means of testing flat-foot. 6. That it is frequently one of the earliest manifestations of flat-foot in booted nations. 7. That while it is commonest in young boys, it occurs frequently in girls. 8. That in the early stages it may be cured by attention to the flat-foot, and by giving room for dorsiflexion of the hallux. In the later stages excision of the proximal end of the first phalanx is probably the only means of cure, though palliative treatment by fixation of the joint may give relief to pain in walking.—*The Birmingham Medical Review*, December, 1887.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 21, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	8	1
Scarlet fever	136	22
Cerebro-spinal meningitis	5	3
Measles	37	5
Diphtheria	161	58
Small-pox	3	3
Yellow fever	0	0
Cholera	0	0

Constipation among the French.—It is not surprising, considering their want of taste for out-door athletic amusements, that our French friends suffer extremely from constipation. The evil effects of fecal retention are therefore strongly marked in the inhabitants of the "gay and festive" capital, with the exception, perhaps, of the anæmia or chlorosis to which Sir Andrew Clark has just drawn attention as a result of fecal decomposition. So universal is the constipation among all classes that, if a tradesman or restaurant-keeper desires to pass off any particular article of food or drink, he claims for it that it is "*rafraîchissant*," which is the equivalent for laxative. The article is forthwith gluttonously devoured. There is, indeed, very little inducement to cultivate a regular habit of the bowels in France. The *cabinets d'aisance* are cramped and uncomfortable when they are not, as they often are, filthy and stinking. Water-closets proper are only to be found at the hotels frequented by English and American travellers, and in the homes of the few Frenchmen who have assimilated English ideas of what is comfortable and right in this respect, or who have married English heiresses. In ninety-nine cases out of a hundred the only water-supply is contained in a ewer, a few drops of which is sprinkled over the pan, the disappearance being facilitated by vigorously rubbing, with the aid of a brush or stick, a piece of furniture which is to be found in the corner of every respectable French closet. From time to time a more thorough evacuation of the bowels is felt to be imperative, and a Frenchman who respects himself will devote at least two days to this important operation. He puts himself on a rigorous diet before and after taking the medicine, and only ventures out when completely reassured as to his fate. It is a recognized case of *force majeure*, and if one wishes to put off an engagement for dinner it is only necessary to write a polite note to the effect that *monsieur* or *madame*, as the case may be, is prevented coming "*ayant à se purger*." As might have been expected, chemists vie with one another to invent the palatable and most reliable purgative, and it can hardly be denied that on the whole it is a more comfortable process than in this country. It is perhaps one of the things they do better in France.—*Medical Press.*

Ergot Valueless in Uterine Subinvolution.—Dr. Blanc has, according to the London *Medical Record*, carried out a hundred observations on the influence of ergotine on involution of the uterus. The preparation employed was the Yvon solution of ergotine injected hypodermically, and the results were controlled by both external and internal measurements. During the ten days following delivery in healthy women after normal labor he found that the process of involution did not take place more rapidly in the women to whom ergotine was administered than in those left to nature, and concludes that ergotine is without effect on uterine involution.

A Busy Practitioner.—Dr. Cotting, of Boston, in relating his personal reminiscences of fifty years' practice, says: "The greatest number of professional visits to separate houses I ever made in one day was forty-three (a few of the houses visited having more than one patient). It was one of the longest days of summer, and there was no time to rest, from early dawn to late at night. I once attended four births, in different parts of the town, within twelve hours; between twelve at night and twelve at noon following. It happened to be a February 22d, and the three boys were each called George Washington, while the girl received the name of Martha. The mothers were unknown to each other."—*Boston Medical and Surgical Journal.*

Programme of Papers and Discussions for the Eighty-second Annual Meeting of the Medical Society of the State of New York, to be Held at Albany, on the 7th, 8th, and 9th of February, 1888.—*First Day—Morning Session* (9.15 o'clock). The President's Inaugural Address. *Papers*—Medical Section: R. Hopkins Buffalo, N. Y., "Idiosyncrasy;" H. Kretzschmar, Brooklyn, N. Y., "Use of Alcohol in Certain Forms of Fever;" J. Leonard Corning, New York, "Neuro-therapeutic Memoranda;" Willis E. Ford, Utica, N. Y., "Reflex Nervous Disturbances;" William S. Ely, Rochester, N. Y. (title to be announced). Surgical Section: Henry G. Gibney, New York, "Mechanical;" Arpard Gerster, New York, "Surgical." *Papers.*

Second Day—Evening Session. The President's Address—Assembly Chamber of the Capitol Building, at 8.15 o'clock.

Dinner—Delevan House, at ten o'clock. (Tickets may be had of the Committee of Arrangements; price, $1.00.)

Third Day—Final Session (9.15 A.M.). *Papers*—Thomas R. Pooley, New York, "Biographical Sketch of the late Dr. Edwin R. Hutchinson, of Utica;" Prince A. Morrow, New York, "Surgical Treatment of Skin Diseases;" Daniel Lewis, New York, "Remarks on the Chian Turpentine Treatment of Cancer;" John O. Roe, Rochester, N. Y., "The Frequent Dependence of Persistent and so-called Congestive Headaches upon Abnormal Conditions of the Nasal Passages."

The meetings will be held in the Court Room of the City Hall, second floor.

The Treasurer, with the Committee on Credentials, will be at the place for meeting and prepared to register members in attendance after 8.45 A.M., on Tuesday. It is requested that as many as possible will attend to this duty before the opening of the session.

Delegates and Permanent Members will meet after the adjournment of the Tuesday morning session, and choose representatives on the Nominating Committee.

At the opening session, a motion will be made to limit the time allowed for reading papers to twenty minutes, and unannounced discussion to ten minutes.

Those intending to discuss any paper will please notify the Chairman of the Business Committee as early as possible.

Officers and Committees of the Society: President—Alfred L. Loomis, New York; Vice-President—A. M. Phelps, New York; Secretary—William Manlius Smith, Syracuse; Treasurer—Charles H. Porter, Albany. *Committees:* Of Arrangements—Samuel B. Ward, Albany, N. Y.; Edward L. Partridge, New York; F. C. Curtis, Albany, N. Y. On By-laws—William C. Wey, Elmira, N. Y.; Henry G. Piffard, New York; William Manlius Smith, Syracuse, N. Y. On Hygiene—E. V. Stoddard, Rochester, N. Y.; A. N. Bell, Brooklyn, N. Y.; H. Curtis, Albany, N. Y.; J. P. Creveling, Auburn, N. ON SOME POINTS IN THE SURGERY OF THE URINARY ORGANS.[1]

By REGINALD HARRISON, F.R.C.S.,

SURGEON TO THE LIVERPOOL ROYAL INFIRMARY, AND LECTURER ON CLINICAL SURGERY IN THE VICTORIA UNIVERSITY.

LECTURE III.

THE OPERATIVE TREATMENT OF STONE AND TUMORS OF THE BLADDER IN RELATION TO SOME RECENT VIEWS AND PRACTICES.

THE surgery of the bladder during the last ten years will, under all circumstances, occupy a conspicuous position in the history of our art by the introduction of litholapaxy, the revival of the supra-pubic, or high operation, under somewhat altered conditions, and by an approach to a more systematic method of treating tumors and growths connected with the interior of the viscus. It has been my privilege to watch the progress of these several procedures, not merely as a passive critic, but as an active participator with others in all the advantages these measures have proposed to confer. Within the period mentioned a vast amount of experience has already been obtained bearing upon these various proposals; and I think the time this evening cannot be better occupied than in drawing some conclusions in regard to them which seem to me may now be fairly and advantageously done. And in referring to these several procedures I will endeavor in speaking of each to indicate what appears to me to be their strong as well as their weak points, and to what extent our present experience tends to show they have justified the anticipations with which they were promulgated. In the course of these remarks I shall not trouble you with statistics relative to operative procedures, as I do not attach much importance to them. It seems to me that in drawing conclusions from figures of this kind, gathered from various sources, we are putting ourselves much in the same position as the individual who, to make sure about the weather, consults three different kinds of barometer, and is rewarded by finding them respectively indicating at the same time "stormy," "rain," and "very fine." From such variations as these most persons would be disposed to conclude, not that it was safe to go out without an umbrella, but that at least two of the instruments must in some respect be faulty. On the other hand, to the collective work of individuals carefully recorded, with all failures and successes, the greatest importance is to be attached, as indicating not only results but how these were obtained.

In the first place, I will take a brief survey of the position that the crushing operation seems to occupy at the present day. Since the procedure which is justly associated with the name of Dr. Bigelow, of Boston, was brought under notice, exactly ten years ago this month, it has been applied to almost every condition under which stone in the bladder is met with in males, females, and children. Without entering into the history of the modern crushing operation for stone, or referring to discussions as to what led up to the important changes it represents, I think most persons will be inclined to admit that the lithotrity of to-day occupies a very different position compared with what it did ten years ago. At the latter date there appeared to be a tendency to limit its application considerably, whereas now we have rather to fear its extension to conditions for which it could hardly have been intended. The removal of a stone at a single sitting, without leaving behind any cause either for its reproduction or for cystitis, represented such a desirable combination of objects as to at once place the matter before surgeons in a light which it had not previously done. Let me stop for a moment to inquire how far this has been realized. In the case of stones of a moderate size, occurring in adults in other respects healthy, I think it will be generally admitted that to these lithotrity may now be applied with a degree of success which prior to this decade had never been obtained in the history of either the cutting or crushing operations. Nor can there be any doubt, excepting children, perhaps, that by far the larger number of stone cases requiring operation occur under these circumstances. But this, unfortunately, does not represent the whole truth, as lithotrity has been and is being applied to a class of cases where the anticipations formed in reference to it in its most modern form have not been realized; and this brings me to notice what I would speak of as the weak side of this proceeding. In corroboration of this, let me read a passage from a recent address by Mr. Cadge:[1] "Although," he observes, "the immediate and direct mortality of lithotrity is small, the recurrence of stone is lamentably frequent. In my own list of one hundred and thirty-three cases there were eighteen in which recurrence one or more times took place, being about one in seven. Sir Henry Thompson, with a much larger number of cases, gives about the same proportion. I am disposed to infer, however, that recurrence is more frequent than this, because it is not likely that all who get relapse apply to the same surgeon again. Patients may, and frequently do, apply to the same operator once or twice, but after a time they either apply to their own surgeon, or they decline further treatment, and too often their subsequent history is one of painful endurance of chronic bladder disease and gradual exhaustion. If, moreover, there be added to the list those numerous cases of phosphatic deposit or concretions so frequently noticed after lithotrity, the relapses would, I believe, reach to nearly twenty per cent. This seems a heavy indictment to bring against lithotrity, but I am afraid there is no gainsaying it, and if so, it would be wrong to pass it over or make light of it."

Though with a very much less experience of lithotrity than been that to which I have just referred, I became impressed some years ago with the conviction that in certain cases we could do something more than merely remove the stone from the bladder.

It will, I believe, be generally admitted that the state of the interior of the bladder relative to its shape, its power of contraction, and the presence or absence of inflammation, has, without being more precise, a determining influence in the reproduction of stone. In the majority of instances this is merely a matter of experience deduced from observation, while in not a few this tendency is not discovered until, as it were, the experiment of removing the stone by crushing and aspiration has been tried and failed. And in connection with this observation, I think, we have been rather too much disposed, if I may judge from a good deal of the literature relative to this subject, to allow the physical properties of the stone to determine for us, as it were, the selection of the operation, irrespective of the relative conditions to which I have referred. Though a large, hard stone is, as a rule, best treated by lithotomy, this by no means implies that some small and soft ones are the less advantageously removed by a similar proceeding.

---

[1] The Lettsomian Lectures, delivered before the Medical Society of London, January, 1888.

[1] Hunterian Lectures, Royal College of Surgeons, 1886.

Let me take, for instance, the case of a stone in the bladder occurring in an adult, with some chronic cystitis and enlargement of the prostate. The probabilities are that for many months, if we look at the section of such a stone after its removal, the bladder has been engaged in incasing it in a mould of phosphates just as completely as if it were done by plaster-of-Paris. Now, is it reasonable to suppose that you can suddenly stop this stone-forming process without leaving behind any contributing cause for its continuance? In connection with the subject more particularly of prostatic hypertrophy, I have examined a very large number of bladders, and, having regard to the distorted or pouched condition of the viscus which so frequently accompanies this change, as well as the condition of the mucous membrane relative to the presence or absence of phosphatic deposit upon it, it has often struck me, not that lithotrity has its failures, but that under these circumstances its successes are so numerous.

Reflections such as these induced me some years ago to gradually alter my mode of procedure in cases of this kind, where either it was clear that the stone was the effect rather than the cause of disease, or where this fact was demonstrated by the failure of lithotrity. I could not help feeling that the bladder, under these circumstances, was not unlike, in many respects, a chronic abscess with a stone in it, and that it was just as necessary to open and drain the one as the other. Let me briefly illustrate this by one of my earliest cases. It was that of a man sixty years of age, who submitted to lithotrity on three occasions in two years, when large masses of phosphatic stone were readily removed. In the intervals between the operations he never was free from vesical irritation. He could not empty his bladder completely without a catheter, the urine was more or less ammoniacal, and, in spite of careful catheterism, he suffered much from urinary irritability. He had some degree of prostatic enlargement, and some pouching or sacculation. Two years after the first crushing, I performed lateral lithotomy for him, and removed more phosphatic calculus of recent formation. I put a large drainage-tube into his bladder, and he was drained and washed for eight weeks, until he voided normal acid urine, when the tube was removed, and the wound allowed to heal, which it did in the course of a month. This patient has now been perfectly well for over three years. I would refer to this and similar instances, not as being examples of successful lithotomy, but of successful drainage.

Three years ago I brought this subject[1] under the notice of the profession, and described at length my mode of operating and of draining; and to these points I would now briefly direct attention. So far as the method of operating is concerned, my object has been to remove the stone by such an incision as will permit the bladder to be readily and efficiently drained; hence, the proceeding stands much in the same light as evacuating matter from a chronic abscess does to the important part of the treatment by drainage that is to follow.

In the performance of lithotomy in cases of this description my aim is to make a wound into the bladder which is not likely to close up before the interior of the viscus is ready for the reception and continence of the urine. Hence, I am an advocate for lateral lithotomy, which best fulfils the conditions that are required. But though the mode of opening the bladder is important, the process of draining, where the condition of the viscus or of the parts above it is such as to require this, is still more so. As a rule, cases of this kind require drainage to be continued from four to eight weeks. I have drained them as long as ten weeks before the state of the bladder, as evidenced by the urine, was such as to allow the wound to heal up. The drainage-tubes I employ for this purpose are larger than those which have been used temporarily by some surgeons after lithotomy, and some care is required in fitting them to each case. By their use, with the exception, perhaps, of the first few days after the operation, when some urine may escape by the side, I have been able to keep patients absolutely dry during the whole process of treatment, while at the same time antiseptic dressings have been applied to the perineum; but I do not attach much importance to the latter, so long as the urine-drainage is perfect.

Let me illustrate this practice by another case of somewhat recent date. It was that of a gentleman, seventy years of age, who for over four years had never passed one drop of urine except through a catheter, and who for the last two years of this period had absolutely lived with the instrument in his bladder, both day and night. I examined him in October last, and found that he had a stone in his bladder, but one that I could have quite easily removed by crushing and aspiration. However, in the presence of the symptoms mentioned, and guided by other experience of the kind to which I have referred, I selected to perform perineal lithotomy, and to drain. My colleague, Mr. Mitchell Banks, held the staff for me, and I removed three uric-acid calculi of moderate size, coated with phosphates. I made, as I usually do, a very free opening into the neck of the bladder, and put in one of my largest-sized drainage-tubes, with two or three superficial sutures in the wound to keep it in position. He was drained continuously for eight weeks, when it was found, coincidently with a much improved state of the urine, that the latter was occasionally forced out spasmodically through the normal channel of the penis. The drainage-tube was then removed, and the wound allowed to heal. Though the function of the bladder has been in abeyance for four years, he has now complete control over his urine, and can expel it spontaneously without any assistance from the catheter, which he has entirely discarded since the operation. At present he has to pass his urine more frequently than is desirable, a circumstance which is probahly due to the empty state the bladder has been in ever since he commenced to use the catheter continuously, day and night, two years ago. Notwithstanding this inconvenience, which, I believe, will improve in time, it is remarkable that the bladder should have entirely recovered its power after such a long period of inaction as four years. Had I crushed, as I could have easily and safely done in this case, I feel sure that the power of the bladder would not have returned in the way that it has.

My friend Mr. Cadge, in referring to recurrences after lithotrity, seems to think that in the matter of treatment we are placed somewhat on the horns of a dilemma; that is to say, if we crush, there is a considerable probability of the stone recurring; whereas if we cut, we adopt a harsh proceeding, and one more immediately perilous to life. As I have said before, I do not attach much importance to statistics, for, putting aside what may be due to the accidents of lithotomy, to which we are all more or less liable, and which are really responsible for no inconsiderable amount of the mortality following this operation, the results will be largely determined by the attending circumstances of the individual case. If a patient comes to be treated for a stone in his bladder with dilated ureters, and with only about one-fourth to one-tenth of his normal amount of kidney-tissue, and the balance made up of pus-cavities, I do not think it makes much matter what you do to relieve the suffering caused by the stone, as the result will be the same whether you cut or crush. Putting cases of this kind aside as being entirely outside the question, just as they are beyond repair, and taking instances where the only objection against lithotrity is that the stones are likely to return or have been proved to do so, I have not observed that the perils of lithotomy are very great.

---

[1] Annals of Surgery, June, 1885.

In analyzing my experience of lithotomy, I can refer to fifteen cases where the process of opening the bladder was followed by a more or less prolonged system of drainage and irrigation, such as I have just described. Of this number, three terminated fatally in the course of from three to five weeks, by reason of the far advanced suppurative condition the kidneys were in. This was considered as probable at the time of operation, and was proved by post-mortem examination. I had no desire to operate at all in these instances, but the patients were in such a painful condition that I had no alternative but to do as they wished, and run my chance. However, as drainage was employed after the stones were removed, I must in fairness include them. In addition to observing the relief that was thus afforded to these persons, I would further remark how importantly they illustrate the disastrous consequences that may ensue when stone and cystitis are complicated with obstruction, or anything that interferes with the process of natural urine-drainage, prior to the removal of the stone. In two of these cases there was some enlargement of the prostate, while the third was complicated with an old urethral stricture. Further, they clearly point to the importance of drainage as a necessary part of the process connected with the removal of some stones. The remaining twelve persons so treated recovered, and remain well, or did so up to the time that I had cognizance of them. I think I should be pretty sure to hear of them if they had any recurrence. Three of these cases had been previously treated by crushing, to one of which I have already referred more in detail. In determining how long it is necessary to continue the drainage, I attach considerable importance to two points—first, to the condition of the urine, and, secondly, to certain muscular actions of the bladder, which become more apparent in those cases where atony pre-existed. So long as a patient goes on discharging ammoniacal or very purulent urine, so long must the drainage be continued, as to close the bladder under these circumstances is certainly to favor the reproduction of those local causes which contributed to the formation or growth of the stone. When the urine is becoming normal, one of the earliest indications that the drainage-tube may be withdrawn is the voluntary, or, I should rather say, the spasmodic, expulsion of urine along the natural passage. After three or four weeks' drainage, according to circumstances, I have allowed patients to get up for a little and sit in a chair, with a clip on the end of the drainage-tube, directing them to remove it when they feel desirous of urinating. It is under these circumstances that urine is sometimes expelled independently of the tube along the natural passage. This I have found a sure indication that the power of the bladder will be restored in those instances where it had been lost to a greater or lesser degree. And it not only applies to cases where a stone is present, as I have illustrated, but to others. This was evidenced in a remarkable way in the following case, which much impressed me at the time, in reference to what opening and draining is capable of doing. It was that of a man aged sixty-eight, who was under my care in the Royal Infirmary in 1883, for an atonied bladder and retention of urine, where the regular use of the catheter had become, in the course of time, extremely difficult by reason of the obstruction. After three weeks' trial of various plans of treatment, I performed perineal cystotomy, divided the prostate, and put in a drainage-tube. This was worn for eight weeks, when it was noticed that a certain quantity of urine forced its way along the urethra. The tube was then withdrawn, and the wound gradually closed. After this, the patient never had any further difficulty in urinating, though the power of the bladder had been entirely suspended for some months prior to the operation and drainage. Six months subsequently, he was seized with hemiplegia, which confined him to bed for the rest of his life, but I ascertained from his medical attendant that it had never been found necessary again to make use of the catheter. Other cases of the kind might be adduced in support of the practice I am now advocating.

In two instances, where the stones were very large, I had to divide both sides of the prostate. I could not help observing that these cases made very rapid progress. It is of much importance that the wound should invariably be made clean and straight, and that the relations of the parts be not unnecessarily disturbed with the finger, as thus pouches are made in which urine may lodge. I should also mention that in one case the progress toward recovery was somewhat retarded by two or three attacks of secondary hemorrhage, necessitating the use of a plug outside the drainage-tube. However, it was not sufficient to be of much importance. In another instance the patient had two or three slight attacks of orchitis, which was probably due to some imperfection in the drainage-apparatus; where the prostate is very irregular this may happen, unless care is taken in making the incision into the neck of the bladder.

In these remarks I have thus endeavored to illustrate what appears to me to be the weak aspect of lithotrity, and what alternative seems to me, from some practical experience specially directed toward this point, best adapted to meet the difficulty. Fortunately, I believe these cases are not now so frequent as they used to be, owing, no doubt, in a great measure, to the better means we possess of detecting stone in the earlier periods of its formation, when it can be dealt with by crushing with the most complete success. To eliminate the cases which are not adapted for crushing is worthy, I am sure, of our most careful attention, and as a contribution toward this I must ask you to accept these remarks.

Turning to another debatable point, I would refer to the application of lithotrity to male children. Some valuable records relating to this operation have been furnished by surgeons practising in India, among whom I may mention Dr. Freyer and Dr. Keegan. The latter gentleman has more particularly demonstrated the great success that may be obtained in boys by the crushing operation, and his testimony has been to a considerable extent corroborated by Mr. Walsham and other surgeons. Having regard to the great success of lithotomy in male children, I should not feel disposed to extend the crushing operation in this direction materially, except in the case of very small stones. It has, I know, been alleged that lithotomy means emasculation, but I am not aware that sufficient proof of this has been afforded. If this were proved to be an occasional and unavoidable consequence, the reasons for crushing in boys would be materially strengthened.

The supra-pubic operation for stone owes its recent revival in a large measure to the observations of Garson, the practice of Petersen, of Kiel, and the advocacy of Sir Henry Thompson. The fact that the bladder is usually uncovered with peritoneum immediately above the pubes has for a long period been rendered available by surgeons for tapping with impunity in cases of retention of urine. To increase this area, and to permit the bladder to be opened and stones removed without injuring or wounding the cavity of the peritoneum, is the chief feature in Petersen's method of performing the high operation. Since the introduction of this method of operating considerable discussion has been excited in reference to the circumstances under which it is applicable, and much variety of opinion has been expressed. If, however, we merely content ourselves by taking the experiences of surgeons where this measure has been practically tested, we shall have no difficulty in determining its value.

In the first place, I do not think that anyone would attempt the removal of a very large stone from the bladder by any other proceeding. We have already had several examples where large masses have in this way been successfully removed, which, judging from previous experiences of the kind, could not have been safely accomplished, even if it had been possible to effect their removal at all. And this applies equally to some cases of distorted pelvis, where the outlet is so contracted as to render perineal lithotomy impossible. I should have been very glad to have availed myself of this method of operating in one of my earliest stone cases some twenty years ago, where I performed lateral lithotomy for a boy with his hip anchylosed in an extended position.

In the second place, experience has already shown us that the supra-pubic operation is well adapted for the removal of certain foreign bodies more or less coated with phosphates from the bladder, where it is necessary that we should be able to see as well as to feel, and direct what we are desirous of doing.

In the third place, the supra-pubic incision may prove serviceable in some cases of stone in the bladder complicated with a protruding prostate, where the removal of some portion of the latter may be further contemplated.

In the fourth place, the high operation will prove to many practitioners an easier and therefore a safer access to the bladder than the lateral perineal route, and thus, for this reason, and in the best interests of their patients, many will avail themselves of it under almost all circumstances. Are not these sufficient reasons for finding a place in surgery for this method, irrespective of the value that most of us, I believe, still attach to perineal lithotomy? I have no belief in the decline of perineal lithotomy, as it seems to me to possess advantages as a ready means of entrance to as well as exit from the bladder, which no other method possesses.

In the controversy that has been recently raging in reference to the relative advantages of supra-pubic and perineal lithotomy, I cannot help thinking that much of the difficulty which some have associated with lateral lithotomy, or Cheselden's operation, is in a measure due to a wrong conception of the way this operation should be performed. The point where it seems to me some surgeons are at variance with the description laid down by authorities on this subject, is in reference to the employment of dilatation with the finger as a means of entering the bladder. I contend that such a process, whether there are grounds for its adoption, so far as the literature of the subject is concerned, or not, is not only unnecessary, but dangerous. It is unnecessary, because the opening into the bladder can be safely made with the knife, sufficient to permit of the finger being put, and not pushed, into the viscus; it is dangerous, because the risk is not inconsiderable of wrecking the operation by rupturing the urethra, especially in young children, and by destroying with the finger the natural relations of the parts. It is a misconception of this kind which alone imports an element of danger, so far as the mechanism of perineal lithotomy is concerned. Of the advantage that the latter operation affords as a means of draining the bladder I need not again speak.

But though, as I have incidentally hinted, supra-pubic cystotomy will probably commend itself to some practitioners by the comparative facility with which it can be accomplished, we must not be unmindful that experience has already shown us that it, like other procedures having the same object, has its own difficulties and dangers. Instances have been recorded where a weakened bladder, under the pressure of distention, has given way, and death has then followed; and similarly, the rectum has suffered in a corresponding manner, but without producing any serious consequences. To most of us, the simplicity and ease with which lateral lithotomy can usually be performed is such as strongly to prejudice us in its favor, in the absence of any special reason to the contrary, such as I have indicated. Still, on the other hand, as I have already said, there are places for both the high and the low operations in the practice of surgery, which they can fill with relative advantage and without fear of clashing.

In the last place, let me say a few words in reference to the treatment of tumors and growths connected with the interior of the bladder. And I would take this opportunity of acknowledging the important services Sir Henry Thompson has rendered, in both adding to and applying our knowledge in reference to this subject. In surveying the literature relating to the operative treatment of tumors of the bladder, and comparing it with some little experience of my own in cases of this kind, it seems to indicate the great caution that is necessary in the selection of cases suitable for operation.

Malignant growths connected with the interior of the bladder are, I believe, just as much beyond the reach of surgery as those which are occasionally seen involving the cavity of the nose; I have in a few instances opened the perineum and explored them with the finger, but beyond giving vent to offensive urine mixed with blood and the débris from the growth, I cannot say that I have seen any permanent good follow, and I am disposed to think, with others, they had best be let alone. If exploration with the finger from the perineum indicates, by reason of the limited connections of the growth, the expediency of attempting its complete removal, if the mass is considerable the supra-pubic incision may with advantage be proceeded with. The value of the perineal incision for drainage has already been demonstrated in several instances of this kind. Still, on the whole, the less intravesical malignant growths are interfered with the better, so far as concerns both the comfort and life of the patient. Of the curable forms of intravesical tumor of the bladder, the simple papilloma or villous furnishes us with an example, and this has undoubtedly within the present decade been brought within the reach of surgery. In the cases of this kind where I have operated, I have been able to accomplish all that I desired by a perineal incision. The following instances illustrate some of the difficulties connected with the diagnosis and treatment of tumors of the bladder. The first was that of a young man I saw in 1883, who was suffering from hæmaturia. I opened his bladder from the perineum, and removed a villous growth, which seemed to occupy the orifice of the left ureter; he was temporarily relieved, but in the course of a month he died of exhaustion in consequence of repeated attacks of hæmaturia. After death, the left ureter was found dilated, the pelvis of the left kidney was also dilated, and contained a villous growth resembling that which I had removed from the bladder.

The other case was that of a middle-aged man, who presented all the symptoms of calculous pyelitis of the left kidney. The pain was so severe that I determined to open and explore the kidney, which I did in the early part of December, 1887. I found the kidney not much larger than natural, but it was simply a bag of pus. I could find no stone or other cause for the renal obstruction. The bladder was examined, but nothing abnormal was detected. The patient had a good deal of hæmaturia after the operation. He got gradually weaker, and died about four weeks after the operation. At a post-mortem examination, a small epithelioma of the bladder was found, which had completely occluded the left ureter, and had thus led to the disorganization of the corresponding kidney. Such are illustrations of some of the difficulties which attend the diagnosis of tumors connected with the interior of the bladder; they certainly seem to indicate the great caution that is necessary in coming to a conclusion that their extirpation should be attempted.

I have now completed the task which you, in your kindness, have imposed upon me. It only remains for me to thank you for the patient and attentive hearing you have given me.

THE TELEPHONIC BULLET-PROBE.[1]

BY JOHN HARVEY GIRDNER, A.B., M.D.,

NEW YORK.

MR. CHAIRMAN AND GENTLEMEN: I first presented this instrument to the profession at a regular meeting of the Academy, on February 3d, last year. I bring it before the Surgical Section again, this evening, because, by certain improvements I have been able to make, it is now perfect, and a year's clinical experience has demonstrated its superiority over all other bullet-probes.

But I also desire to ask your attention, for the first time, to the novel and interesting principle on which the instrument is operated, viz., by a current of electricity extracted from the body of the patient himself, in whom it is desired to locate a metallic missile.

The construction of the telephonic probe is as follows: To each of the two terminals of a telephone receiver, *A* and *B*, Fig. 1, an insulated flexible wire about four feet long is connected.

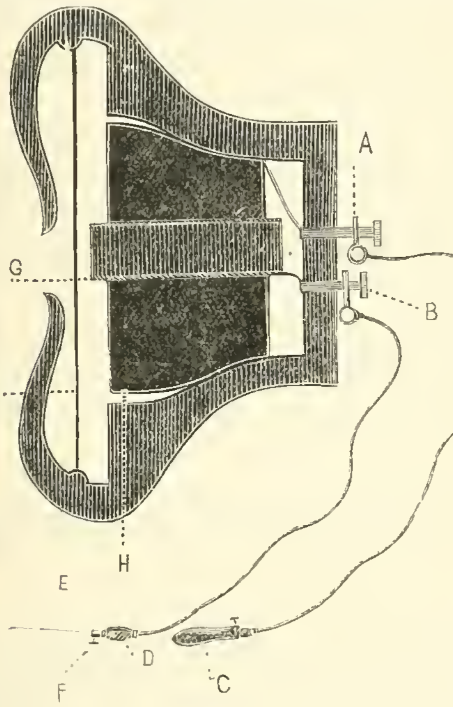

FIG. 1.

At the free end of one of these wires a hollow, bulbous piece of steel, *C*, is attached. At the free end of the other wire is a suitable handle, *D*, in which a probe, *E*, may be placed, and held by the clamp-screw *F*.

The internal arrangement of the handle must be such that a perfect electrical contact shall exist between the end of the probe and that of the wire which terminates in the handle; the same is true for the end of the other wire and the steel bulb.

The receiver R, Fig. 1, is shown in perpendicular section. The framework is of hard rubber, and the internal construction is as follows: In the centre is a small bar of soft iron, marked *G*; around this bar a coil of insulated wire, *H*, is wound; the two ends of the coil pass backward and connect with the terminals or binding-posts *A* and *B*; the end of the soft iron bar is seen to protrude a little beyond the coil, and near it, though not in contact, is suspended a metal diaphragm, marked *I*. Now if a current of electricity be passed through the coil in the receiver by means of bulb *C*, and the probe *E*, a magnet will be made of the soft iron bar *G*, and it, in turn, will attract the metal diaphragm *I*, causing it to vibrate, and each time the current is made and broken a clicking or rasping sound is heard in the receiver held to the ear.

Fig. 2 shows two such receivers as I have described, attached to a flexible steel band; the short wire seen in the cut passing from one receiver to the other is to complete the circuit between them. When the steel band is placed over the top of the head, the receivers fit snugly against both ears, as seen in Fig. 3.

This arrangement has the advantage of leaving both hands of the operator free, it also shuts out all sound except that heard when the bullet is touched. A single receiver, however, held to the ear with one hand, leaves the other free, and answers perfectly for all practical purposes. A single receiver might also be held to the ear by means of an elastic band, such as is used to hold a head mirror.

So far as I know, only the single instrument is to be found for sale in the shops at present.

We pass now to the practical application of this instrument.

To illustrate, I will describe a case seen in practice: A musket-ball had lain between the tibia and fibula for twenty-two years. A long, narrow, tortuous sinus had been discharging for a year. When an ordinary probe was passed, hard substances could be felt in many places; but you could not tell if bone or bullet was being probed. The porcelain-probe could not have been marked by the lead, owing to thick crusts of salts of lead with which the ball was covered, even if it could have been brought into contact with the bullet, which it could not, owing to narrow places in the sinus.

The telephonic-probe was now brought into requisition as follows: The steel bulb *C*, Fig. 1, was placed in the patient's mouth and the lips closed; the operator held the telephone to his ear, while at the same time he passed the steel probe *E*, of the other wire, into the sinus. Bone and other tissue were felt as the probe passed to different parts of the wound, but no response was heard in the telephone until the leaden bullet was touched, then an electric current passed through the telephone; and as often as this current was made and broken, by touching and removing the probe from the lead, so often was there a vibration of the diaphragm, and consequently a clicking and scraping sound heard in the telephone; in other words, the patient's body was converted into an electric battery; the body corresponded to the cups, its fluids and heat to the battery fluid, the

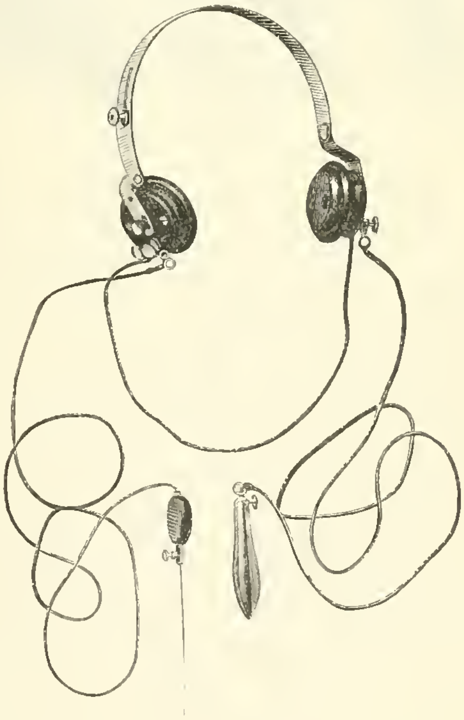

FIG. 2.

---

[1] A paper read before the Surgical Section of the New York Academy of Medicine, January 9, 1888.

steel bulb immersed in the mouth to the zinc, let us say, and the lead, when it was touched, to the carbon, and thus our battery was completed, a current obtained, and the metal diaphragm made to vibrate.

In order that you may test the instrument I will place the steel bulb in this boy's mouth and a piece of lead in his moistened hand; along with the lead I also place a piece of bone in the hand, and you will observe that no response is heard when the bone is probed, but the slightest touch on the lead produces a distinct click or scraping noise in the receiver.

The steel bulb may be placed in the mouth, the rectum, the vagina, or held in the hand, provided the latter is thoroughly moistened, and grasps the steel firmly.

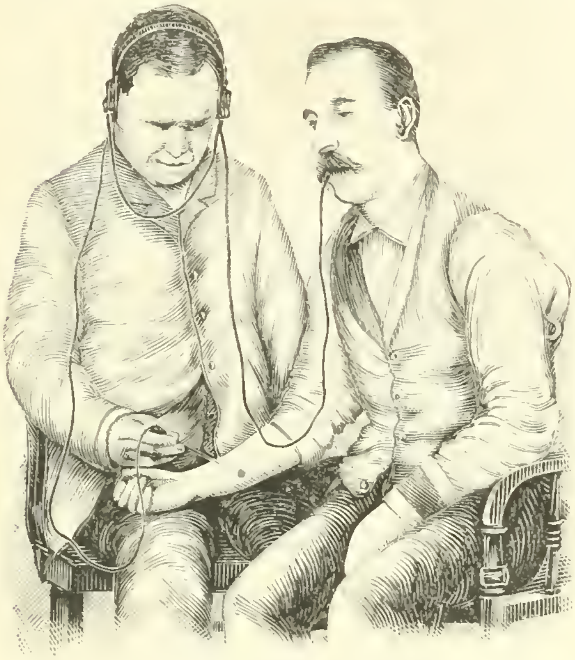

FIG. 3.

A probe or needle of any metal, shape, or character desired, may take the place of the steel probe now in the handle, provided the bulb at the end of the other terminal be of the same metal as the probe, and both differ from that of the missile to be located.

The advantages of this instrument over all others at once appear, when it is remembered, that in its use the accurate sense of hearing is substituted for that of the sensation communicated to the hand, which is always unreliable, for no one can tell if a hard substance felt in a wound be bone, metal, or some other hard tissue.

The porcelain-tipped probe was made with the hope of overcoming this difficulty; but after ample experience with the Nélaton probe, both in my own hands and in those of others in my presence, I am certain that, unless the bullet is perfectly clean from grease, lead salts, etc., and very favorably situated, it is not possible to obtain lead markings on the porcelain tip which can be relied upon to direct our operative procedure. Let any one hold a bullet in the hand, and probe it with a Nélaton probe until the markings of the lead on the porcelain point are perfectly distinct, and he will find that it requires an amount of force and pressure in rubbing the lead which he will rarely be able to make, even in the most favorable cases of gunshot-wound. None of the above conditions, which make the Nélaton probe useless, in any way interfere with the perfect working of this new probe, for you see in the experiments which you are now making on the boy, that the slightest touch of the bullet with the probe causes a loud and unmistakable sound in the telephone. Another great advantage is, that a sharp, slender, steel needle may take the place of the blunt probe now in the handle, and then no tract is necessary in probing; the needle, rendered aseptic, may be thrust into the tissues like a hypodermic needle, with little pain, and no danger to the patient, as I have verified in actual practice, and when the bullet is struck, you have only to loosen the clamp-screw and remove the handle, allowing the needle to remain fast in the tissues, with its point still in contact with the missile, and it serves as a perfect guide in cutting down on the bullet.

We have, then, in this instrument, a simple, cheap, and absolutely accurate means of determining the presence or absence of a metallic missile in a wound, for it responds equally well to iron or other metals as to lead.

Another feature of much interest to me, in connection with the instrument, is the facility with which we obtain a current of electricity, sufficiently powerful to operate the instrument, from the body of the person operated on, as you have seen in the case of this boy on whom you have been experimenting to-night.

This fact, it seems to me, opens an important field for thought and experiment. I have found already that the strength of the current, as indicated in the receiver, varies in different individuals, and in the same individual under different conditions.

When we reflect on the chemical processes which are constantly taking place in the living body, and which exceed in extent and variety those of the most powerful electric battery, the above ascertained facts seem to hold out a hope that we may yet discover such electrical differences in healthy and diseased tissues as will greatly aid in the diagnosis and treatment of diseases.

Dr. Franklin sent his kite into the clouds to obtain a spark for experimental purposes. In our day, we find that the living human body yields a current of electricity which can be utilized for a practical and humane purpose.

THE ORTHOPEDIC TREATMENT OF PARALYSIS OF THE ANTERIOR MUSCLES OF THE THIGH.[1]

By A. B. JUDSON, M.D.,

NEW YORK.

We occasionally meet with cases of infantile paralysis in which the patient has lost the power of keeping the knee stiff in the straight position. When such a patient balances himself on the affected limb, a slight blow, or a touch from behind in the popliteal region, flexes the knee and brings the patient to the ground, unless the fall is prevented by sudden action on the part of the unaffected limb. The deficiency is in the anterior muscles of the thigh. The patient, when sitting on the edge of a table, has no power to swing the foot forward, because the muscles which should act on the tibia, through the patella and ligamentum patellæ, are paralyzed. A child thus affected will sometimes manage to walk by forcibly grasping the lower part of the thigh with the hand, in order to hold the knee extended at the critical moment when the weight of the body descends on the affected limb, or he will perform locomotion in a curious manner by advancing alternately the heel and the toe of the well foot, the affected foot trailing on the floor behind. But walking, in the ordinary sense of the word, is impossible, and, unless relief is afforded, the child is thrown on crutches, and the limb is consigned to atrophy and total disability. The hip-joint, the ankle-joint, and the foot may all be well able to sustain the weight of the body, but if the knee is unable to hold itself straight the limb is utterly useless in locomotion. A defect here, like the removal of the keystone of an arch, sends the whole structure to ruin. Disuse leads to defective circulation. The hamstrings contract. The limb hangs useless, it suffers from cold and is liable to chilblains, and in various ways is such an annoyance that, when the patient reaches years of discretion, amputation is demanded and performed, as happened in two cases which I can recall. The desperate condition of these patients is further illustrated by the fact that exsection of the knee has been repeatedly performed to secure anchylosis in the straight position.[1] Dr Thomas G. Morton[2] ingeniously formed a stump for the application of an artificial leg by flexing the leg on the atrophied thigh and binding the two together, the foot being in contact with the natis. If these patients had been furnished, from the early age at which infantile paralysis occurs, with a splint which had the power to keep the knee stiff in walking, the circulation would have been encouraged, the limb would have developed to a fair degree, contraction of the hamstrings would have been prevented, and adult age might have been reached with such a degree of stability in the knee-joint that the apparatus might have been discarded.

---

[1] Read before the Orthopedic Section of the New York Academy of Medicine, January 20, 1888.

I desire to present a very simple splint, designed to keep such a limb straight during locomotion. Retentive force applied at the points and in the directions indicated by the arrows in Fig. 1 will keep the limb straight, and this is accomplished by the splint which is represented in Fig. 2.

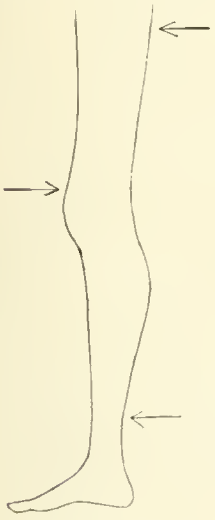

FIG. 1.

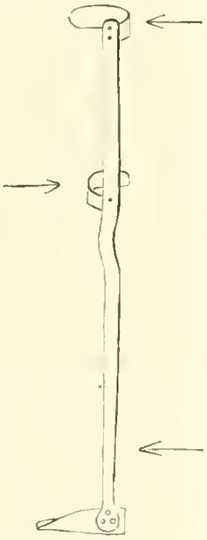

FIG. 2.

I do not say that this is not done by other splints. Some of them, however, have so many buckles, straps, movable joints, artificial muscles, and springs, that they are often inefficient and require frequent repairs. The one which is here described can hardly get out of order, and requires attention only when it is outgrown. I therefore make no apology for devoting a few lines to describing its details. In practice the details are quite as important as the principles involved.

In the first place, the splint should be made of tractable steel, so that it may be bent to fit the limb smoothly and avoid the bony prominences of the knee and ankle. The upright may lie on the outer or the inner side of the limb, the choice being decided by the condition of the ankle. As a rule, these cases show some muscular deficiency at the ankle-joint. The lower part of the splint is therefore practically a club-foot shoe, to be applied on the outer side if the foot inclines to valgus, and on the inner side if the tendency is toward varus. As in the adjustment of an ordinary club-foot shoe, buckles and webbing are to be applied to oppose whatever deformity exists at the ankle. The buckles and straps are not shown in the cut. They are to be attached at such points and in such numbers, and with such changes from time to time, as will produce the desired effect on the ankle. However applied, they will at once fasten the lower part of the splint to the foot in such a manner that when the entire apparatus is adjusted a retaining force will be exerted at the point and in the direction indicated by the lowest of the three arrows.

The upper part of the splint, as shown in the figure, is so simple that it hardly needs a verbal description. Steel bands of tolerable firmness, each long enough to more than half encircle the thigh, are riveted to the upright. The splint is readily applied by placing it against the middle of the thigh, with the upright at right angles with the femur. Then, when the upright is brought down parallel with the limb, the two bands will find bearings—the upper one against the upper and posterior, and the lower one against the lower and anterior part of the femur. The application is then completed by buckling the straps of the foot-piece. The bands will retain their hold of the limb without the help of straps and buckles. If hyper-extension of the knee is present in too great a degree, it may be opposed by the addition of two straps, one crossing the upper and anterior part of the thigh, and the other attached to the free end of the lower band, and crossing the popliteal region obliquely, to be buckled to the upright below the level of the knee. It is clear that the shape of the bands is a matter of the greatest importance. As a rule, it may be said that they should be curved in such a manner that, when the splint is looked through endwise, the lumen formed by the two bands should not very much exceed in its antero-posterior measurement the diameter of the shaft of the femur.

The bands and that portion of the upright included by them may be wound with a strip of gum-plaster to prevent rust, and then with canton-flannel, muslin, or silk. The stocking will interpose between the skin and the lower part of the splint. The foot-piece, which is covered by the patient's shoe, is to be lined with plaster and a piece of leather fastened with two rivets. When the patient grows, and the length of the limb makes it inconvenient to sit with the knee extended, a joint may be added to the splint, at the level of the knee, with some device for locking in the straight position when the patient rises.

It may be said that the steel bands should be thickly padded. In reply, I would say that, after many experiments with padded apparatus of different kinds, I have come to the conclusion that a brace is to be made comfortable, not by the addition of wadding, but rather by properly distributing the pressure which it makes. In general terms, whatever retentive pressure is to be made on the bony prominences in the vicinity of the joints should be made, not by the metallic portions of the brace, but by straps of webbing which should draw the deformed parts into a concavity formed by bending the steel frame of the brace. But when pressure is to be made on the shafts of the long bones, which are, as a rule, provided with a natural pad of muscular and cellular tissue, the metallic portion of the brace may be brought in contact with the skin, with the interposition of a slight layer of some protective material. But in such cases great pains should be taken to bend and twist the steel until the entire surface of contact is evenly applied to the bony surface.

The custom of lining braces of all kinds with pads and cushions is to be deprecated. Too often they accomplish very imperfectly what could be perfectly done by properly bending or twisting the steel frame of the brace. The best way to reconcile the patient to the inconvenience of wearing a brace is to furnish one which is of service in assisting locomotion or preventing pain. Such a brace may of necessity be heavy, unsightly, and harsh to the unaccustomed skin, but the patient will be eager to wear it as soon as he perceives the fact that the pleasure and comfort and convenience attending its use outweigh the inevitable discomforts. I have seen many instances in which thick and elaborate pads have been voluntarily discarded in favor of hard and simple coverings more in accord with the patient's own idea of comfort, cleanliness, and convenience.

---

[1] Dr. Stephen Smith: Transactions of the New York State Medical Association, 1884, vol. i., pp. 322–327. Dr. Ap Morgan Vance: New York Medical Journal, November 7, 1885, pp. 512–514.
[2] Philadelphia Medical Times, April 8, 1882, pp. 473, 474.

The splint here described is not to be worn at night. It is to be applied as soon as it becomes clear that the anterior muscles of the thigh are permanently incapacitated by the paralytic attack. Without it, or its equivalent, the patient can walk only with the help of crutches, and then only with the burden of a worse than useless limb. With the splint the paralyzed limb resumes its duty and the crutches are thrown away. If, perchance, both of the lower extremities are affected in this way, a splint of this kind is to be applied to each limb. Without them locomotion is possible only by the hands and arms as the patient sits or lies on the floor, and a wheel-chair or a bearer becomes in time a necessity. But with the splints the limbs resume the power of sustaining the body in the erect position, and locomotion with crutches becomes practicable.

It is not to be expected that patients wearing a splint for paralysis of the anterior muscles of the thigh will walk with perfect ease and grace. The advantages of the use of the splint are to be found in a greater ability to walk and in the good condition of the limb, which is secured by its constant use from infancy. I have a number of patients under treatment as above described. The case which best illustrates the usefulness of this splint is the one which has been under observation the longest. A girl was attacked with infantile paralysis when two years of age, in August, 1875. In 1877 the splint was applied. At that time the patient presented a typical case of the kind under consideration. The thigh was extremely atrophied. She could not walk, nor could she, without the splint, put her weight on the affected limb. At the present time, the girl being fourteen years of age, the limb is well nourished and fairly developed. There is no contraction of the hamstrings. There is no deformity except what comes from shortening and paralytic flat-foot. She can take a few steps without the splint. The articular surfaces of the knee are broad and kept in perfect coaptation, and she is likely to have a very useful limb when she reaches maturity.

The evident simplicity, moderate cost, and durability of this splint are points in its favor. But because it is simple in its construction it does not follow that its application and proper adjustment are matters that may be lightly dismissed. We find the skeleton of the lower extremity unable to support the weight of the body, and seek to re-enforce it by a supplemental skeleton of steel, the two to be brought together with the interposition of the sensitive skin. The problem, like many which present themselves in orthopædic practice, requires time, a practised mechanical sense, and good-natured and patient attention to details.

42 East Twenty-first Street.

Gymnemic Acid.—In a London letter to the *Journal of the American Medical Association* it is stated that a new acid has been discovered, which removes temporarily the capability of tasting sweet and bitter substances. The credit of the discovery is due to Dr. D. Hooper. The acid is derived from an Indian plant, the *gymnema sylvestra*, one of the family of the *esclepiadiæ*. If a few drops of the acid, well diluted with water, be taken into the mouth, and a sweet substance be eaten two or three hours afterward, no taste of sweetness will be perceived. Under such circumstances gingerbread only tastes of ginger. If a sweet orange be eaten, only the acidity can be detected. Sulphate of quinine, taken after a few drops of the diluted acid, gave the sensation of "so much chalk" only. It has, therefore, "anti-bitter" properties, also. Dr. Hooper finds the substance similar in many respects to chrysophanic acid. The name *gymnemic acid* has been given. Dr. Hooper thinks it will be a valuable addition to the pharmacopœia in disguising the taste of nauseous drugs.

SOME CLINICAL POINTS ON GASTRECTASIA.

By A. A. SMITH, M.D.,

NEW YORK.

With a view to eliciting a discussion of the subject of dilatation of the stomach, I venture some remarks, more especially of a clinical character. I do not expect to relate the history of a case in which a pouch of the stomach was found protruding down into a scrotal hernia, although such a case has been reported; nor have I the history of a case whose stomach contained ninety pounds of matter. Such a case was related two hundred and fifty years ago. It is difficult to determine the limits of the stomach's capacity, both as to the quantity it may contain and its power to digest. I have no doubt there are many stomachs which are dilated moderately, and yet are capable of performing their functions fairly well.

All observers admit that obstruction at the pyloric extremity of the stomach, usually of a malignant nature, is the most frequent cause of dilatation. So well recognized is this, I will not dwell on it further. The obstruction may not be in the stomach itself, but is frequently only in the vicinity of the pylorus; indeed, a growth in any of the adjacent viscera may mechanically obstruct the free egress from the pylorus of the partially digested food, and in this way cause dilatation. A very unusual case of this nature occurred in the practice of the writer. A gentleman, past sixty years of age, had for many years suffered from attacks of disturbance of digestion, characterized by nausea and vomiting, severe gastric pain, and obstinate constipation. He was always relieved by the vomiting. During the last two years of his life he was under the writer's care. He had, during the first year, several of his attacks of so-called indigestion, with the characteristics named. During the last year of his life his attacks became more frequent and more prolonged. Along with this there was progressive loss of flesh, and a cachectic appearance very suggestive of malignant disease of the stomach, but there were never any physical signs of it. Dilatation of the stomach was easily recognized. During these attacks, when he had been free from vomiting for three or four days, at the end of that time I have more than once seen him, in an attack of vomiting, fill a four-quart vessel with the vomited material. As is usual in such cases, the vomited matter was always acid and of foul odor. He died from exhaustion; starved to death, as he himself suggested he was doing.

The autopsy was interesting. The stomach was enormously dilated. There was no cancer of stomach; none of intestines. The gall-bladder had become adherent to the duodenum, and the two viscera communicated by an opening three-fourths of an inch in diameter. The gall-bladder was contracted around a number of gall-stones, one of which nearly occluded the cystic duct. The gall-bladder was situated back of the ribs in such a way that it could not be detected during life. The pressure of one large gall-stone, which remained in the opening between the gall-bladder and the duodenum, diminished the size of the pyloric opening so much that the little finger could be passed with difficulty.

There are some cases of gastric dilatation in which there is no pyloric obstruction, and which, it seems to me, are of much more interest than those in which such obstruction is found. It is not always easy to discover the etiology in such cases. To say that it is due to some weakness in the muscular coats of the stomach is simply to name one of the conditions which accompany the dilatation. What may be the underlying cause is not always easy to discover; indeed, in some of them the cause cannot be discovered, and we must be content to only conjecture.

The recognized causes of dilatation, besides those named (which include mechanical obstruction at the pylorus, either from within or from without the stomach), are any interference with the peristalsis of the muscular coats, such as peritoneal adhesions either slight or over a large surface, adhesions to the surrounding viscera, the weight of a hernia, and other causes of displacement of the stomach or portions of it, and interference with the proper chemical functions. This last may always, or nearly always, be included in any one of the other causes. As long as the chemistry of digestion remains normal, dilatation cannot be considered to have progressed to a serious extent. Even where there is evident mechanical obstruction the chemical disturbance of digestion has usually, if not always, much to do with the production of dilatation.

There are still other cases in which none of the causes named can be found. I have seen two well-marked cases in rachitic children—not simply the ordinary big abdomens of rachitic children, but all the physical signs of dilatation of the stomach. In one the child, five years of age, could drink three pints of fluid and allow the marking out of a line two inches below the umbilicus. No satisfactory explanation has yet been given of the causes of dilatation of the stomach in a rachitic child. There would seem to be some loss of muscular power in the stomach-wall belonging to the disease, and this, combined with the interference with the digestive processes allowing of fermentation, causes the dilatation. We must be content in such cases with the rather indefinite explanation, malnutrition and impaired innervation.

The question of neuropathic influences in its relation to dilatation of the stomach would lead us somewhat into the domain of theory, yet it seems reasonable to suppose it may be concerned in producing it. Section of the pneumogastrics in the neck paralyzes *nearly*, but not *entirely*, the muscular coats of the stomach. When the section is made in an animal in full digestion, the stomach-digestion is almost completely arrested.

Again, injury to the splanchnics is well known to interfere with the proper natural progress of the food from the stomach. If from any cause the stomach is not able to empty itself in the usual time of digestion, and such delay is kept up constantly, it will at least favor the occurrence of dilatation, if not absolutely produce it. I have seen two cases of gastric dilatation in Bright's disease in which there was cardiac enfeeblement. To be sure, the dilatation was not to an enormous degree, but was sufficient to at times give much distress. Of course in this disease, after it has advanced to certain stages, there is almost invariably great disturbance of the chemistry of gastric digestion. May there not be some influence produced by the poison on the pneumogastric in its course, or at the point of its origin in the medulla, producing impairment of innervation to the organs to which it is distributed?

We see not infrequently moderate degrees of gastric dilatation co-existing with enfeebled heart in gouty subjects, without there being any well-defined cardiac lesion. May not impaired innervation explain both conditions, the cardiac enfeeblement and the gastric dilatation?

The diagnosis is not difficult where the dilatation is marked and due care is shown in examination; especially is this true if there be a moderate accumulation of gas in the stomach. It would hardly be in place in a paper like this, limited as to time, to discuss fully the symptomatology of gastric dilatation. I can only refer to a few prominent features. Always there are symptoms referable to the stomach, which direct our attention to it as the probable seat of trouble. Symptoms of gastric fermentative dyspepsia are prominent, but these are also present in many cases of gastric disturbance in which there may be no dilatation. Pain is rarely ever a prominent symptom of the dilatation *per se*.

Vomiting is not always present, but when present it gives strong evidence in favor of dilatation. The character of the vomited matter, the quantity and the intervals of vomiting, seem to me to give stronger evidence of dilatation than any other symptom. The quantity is very significant. In no other disease is there such a large quantity vomited at one time. The interval between the acts of vomiting is usually two to four days; this allows of the accumulations to occur. The vomiting is usually followed by temporary relief. As the dilatation becomes more marked, frequently the intervals between the acts of vomiting become longer, but the quantity greater. In the vomited matter often there will be portions of food undigested, and which was swallowed, it may be, two or three days previously. If the vomited matter contains food eaten the day before—and this occurs frequently—I am suspicious of dilatation of stomach. As to the character of the vomited matter: It gives evidences of fermentative processes. It is acid, sometimes intensely so, usually extremely offensive, contains food in various stages of digestion, and under the microscope shows presence of sarcinæ ventriculi and the yeast-fungus. We cannot, however, lay too much stress on the fermentative processes, as they occur very frequently in undilated stomachs; but, as I have already said, the chemical disturbance of digestion is a very important factor in every case of gastric dilatation, and our treatment must be chiefly directed to it.

Another prominent symptom I have observed is, in some cases, a great craving for food, even though such large quantities are taken. This is easily accounted for. The food taken is not digested, consequently the patient is practically in a condition of partial starvation.

Physical exploration, however, is usually necessary to a diagnosis. If the stomach be largely dilated and moderately distended with gas, inspection will reveal abnormal prominence in the epigastric region, more marked on the left side. If the muscular walls of the abdomen are relaxed, and the stomach is not distended with gas, there will be no evidence whatever by inspection.

Occasionally a peristaltic wave may be seen passing from left to right across the epigastric region. This is said to occur only when there is decided hypertrophy of the muscular wall of the stomach. I saw this very well marked in a case recently under observation. A slight tap on the abdomen, the application of cold, even the mere passing the hand over the abdomen, sometimes would cause it. In some cases the presence of prominence due to the large accumulation of food may be recognized by inspection, especially when the patient is in a sitting posture. The disappearance of this after an attack of vomiting or washing out the stomach may be noticed.

Palpation may give quite distinct evidences if the stomach be moderately distended with gas. Under such circumstances the sensation is something like that which one gets when pressing on an air-cushion.

If there be much fluid in the stomach, and the abdominal walls be quite relaxed by having the patient in a standing or sitting posture, fluctuation may sometimes be detected at the most dependent portion. This is sometimes so easily recognized that the lowest point to which the stomach has extended may be made out by this method.

When there are both gas and fluid in the stomach a splashing sound may be heard, and the movements of the liquid felt, if sharp, quick pressure with the hands, alternately, on the abdominal walls, be made. While much importance is attached to this by most observers, it seems to me to have but little significance. I have often observed it in healthy persons. I have again recently tried this in a number of persons in whom there was no evidence whatever of gastric dilatation, and am convinced it is a sign of but little value. I caused patients to swallow two pints of water, allowed them to move about for a while, and invariably succeeded in the recumbent, standing, and sitting posture, in getting very loud and distinct splashing sounds. I have tried it with milk with the same results. If these splashing sounds continue for five or six hours after a meal, they may be of greater significance.

If the dilated stomach be moderately distended with gas, the tympanitic percussion-sound will extend over a very large area. It does not extend far into the right hypochondrium, but does in the left, often several inches beyond the rib-border. It extends far down into the abdomen, but it is not always easy to distinguish it from a distended large intestine. I have found percussion a very useful aid in this way. When the stomach is empty let the patient drink a quart of water, percuss him in the standing position, and keep on percussing him, as he leans back over a bed or table, until he gets in an almost recumbent position, then let him resume his upright position, still percussing him. The changes from tympanitic percussion to flatness, as the water gravitates to the most dependent portion of the stomach, will enable one to mark quite accurately nearly the lowest line of distention.

I have never been able to recognize the fine crackling or sizzling sound spoken of first by Pauli.

It is important to recognize commencing dilatation, if possible. It is probably frequently overlooked. Disturbances of stomach-digestion are very frequent, dilatation of stomach comparatively rare. Fermentative gastric dyspepsia is frequent without gastric dilatation, and yet fermentative digestive disturbances are very prominent features in dilatation. In the treatment of dilatation our efforts are directed chiefly to the relief of these fermentative changes, whether they are causes or results. Even in dilatation due to mechanical obstruction, great relief may be obtained often by appropriate treatment.

In the way of prophylactic treatment (excluding, of course, mechanical obstruction and incurable organic disease) much may be done, and in the way of correcting all such habits of living as tend to cause gastric dyspepsia.

The timely and judicious management of chronic gastric catarrh, and any other form of gastric disturbance accompanied by fermentative processes and delayed digestion, is of great importance. As to food, it is difficult to lay down arbitrary rules. In a general way it may be said, food which ferments easily should be avoided. Sweets and farinaceous articles seem especially objectionable. I have found, too, milk is usually not well borne if the dilatation is marked, and the same may be said of most vegetables. Food which is easily digested, and in concentrated form, should be given, and the intervals between meals should be short. An almost exclusive meat and fatty diet has worked well in some cases. Food which has been partially digested, artificially, before administration aids in some cases.

The prevention, as far as can be, of distention of stomach by its contents, whether this be in the way of the quantity of food taken, or from gases the results of fermentation, must be favored.

Washing out the stomach has occupied a very important place in the treatment of such cases since Kussmaul first suggested its systematic use. While it has not fulfilled the promise first held out, it nevertheless is of great value in some cases. It has taken its place among means of treatment not only in this but in other forms of gastric disturbance, and is likely to remain. In far advanced cases it can only give relief, it seems to me. Its good effects in the relief of chronic gastric catarrh are well established, and as chronic gastric catarrh is almost always present in cases of dilatation, its beneficial results are often very marked. It can be considered only an aid to other means of treatment.

Electricity has as yet given negative results, and as it is used generally only in connection with other treatment, it is difficult to say whether it is of benefit.

As to medicinal agents, they can be of service only in relieving the conditions which give rise to dilatation or accompany it. There is no drug or combination of drugs which can restore the muscular power to the stomach-wall when such power is once absolutely lost.

Such as aid the digestion, especially those which aid in preventing fermentation, are useful. The salicyl series, including creasote and carbolic acid, have sometimes seemed to benefit. Mineral acids, too, sometimes, give great relief. Alkalies before the taking of food have seemed to me sometimes to be beneficial. Pepsin is of doubtful efficacy, although in some cases it seemed to aid digestion. These agents seem to be more beneficial after washing out the stomach than before, whether this be due to the fact of their having a better opportunity to act, or perhaps the benefit may be due to the washing out alone. Nux vomica, from its well-known action on muscular fibre, has more advocates than any other one remedy, but it is doubtful if its good effects can be attributed to anything more than its general tonic influence.

An occasional cathartic is beneficial, especially the cholagogues. Sometimes the saline cathartics seem to act more beneficially than any others. Those which I have found most beneficial are the Friedrichshall and Rubinat-Condal waters.

ALONZO CLARK, M.D.

A MEMORIAL READ BEFORE THE ACADEMY OF MEDICINE ON JANUARY 5, 1888.

By FRANCIS DELAFIELD, M.D.,
NEW YORK.

MR. PRESIDENT AND FELLOWS OF THE ACADEMY OF MEDICINE: It has become the custom among us that, as one after another of the leaders of the profession passes over to the majority, carried from us by relentless death, an account of the life of each should be read before the societies to which he has belonged, so that those of us who survive may profit by their examples, may avoid their errors, may be incited to emulate their achievements.

The performance of such a pious duty to-night has devolved on me—would that it had fallen to the lot of one better fitted for the task. Yet let me entreat of you to remember that the poverty of the discourse will be due not to the theme, but to the speaker.

Dr. Alonzo Clark was born in Chester, Mass., on March 1, 1807. He died in New York City on September 13, 1887. In the year 1855 he was made Professor of Pathology and the Practice of Medicine in the College of Physicians and Surgeons. In 1882 he gave his last lecture at the College.

His real life was all contained within the period of years between 1855 and 1882—the period during which he taught and practised medicine. Before this his life was one of preparation; after this only a waiting for death.

His life of preparation was that of so many other Americans. The determination to obtain a thorough education, without the necessary means for this purpose, involved with him as with others the necessity of being at the same time a scholar and a teacher—a scholar to educate himself, a teacher to earn his means of support. No better men are turned out by our colleges than those who are educated in this hard school.

With Dr. Clark the pressure of poverty was not felt until he was in his sophomore year at Williams College. But from that time until he was established as a teacher of medicine this pressure was always felt, and had its effect in moulding his character. While at college he taught for six months at a school in Northampton; after graduating he taught at Northampton and at Williamstown.

Then he came to New York to prepare himself to teach chemistry, and entered the College of Physicians and Surgeons. Still he had to teach, and did so in some of the New York schools.

The chair of chemistry, for which he had been working, was given to another, and then for the first time he resolved to embrace the profession of medicine—curiously enough, with the idea of becoming a general practitioner.

He took his degree as Doctor of Medicine at the College of Physicians and Surgeons in 1835. For two years after this he was an *interne* at the New York Hospital.

In 1837 he went to England as the medical attendant of Joseph Bonaparte, and continued his studies first at London and afterward in Paris.

In 1838 he returned to America, and then went with Mr. Arthur Baring to Madeira, where he remained five months. Then he again spent several months in Paris and London.

In 1839 he once more went to Europe, with Mr. James Boorman, and at that time travelled over many countries.

Of his life in Paris I have obtained some account from Dr. Stillé, of Philadelphia.

In the year 1836 there was gathered together in Paris a little company of American medical students, many of whom at a later time attained eminence in their profession. Drs. Bowditch, Holmes, and Shattuck, of Boston; Dr. Swett, of New York; Drs. Gaillard and Porcher, of Charleston; and Dr. Stillé, of Philadelphia, were among the number.

Even in such a company as this Dr. Clark's superiority seems to have been felt. Dr. Stillé's "Journal" speaks of him as follows:

"Clark was our senior by five or six years (he was then twenty-nine years of age), his manner was impressive, and his serious tone gave him a sort of supremacy within our little circle. I was associated with him in clinical studies, and was impressed by the laborious process through which he acquired knowledge, by its precision and accuracy. He had learned the value of time and thoroughness in the school of experience. His self-poise and absolute integrity inspired his associates with a feeling compounded of love and respect. The more so, perhaps, that in the midst of a social circle that did not allow science to exclude devotion to pleasure he never indulged in any of the dissipations which most of his companions used as a relaxation to severe study, and yet he never set himself up as a *censor morum*. His circle always gave him the title of 'Father Clark.'"

Dr. Clark's medical studies in Paris and London seem to have been prosecuted especially with reference to the knowledge of disease. The bedside and the dead-house were the places where he studied, and books and authorities, although not neglected, were as nothing compared to what he could see and hear himself.

In the year 1840 he returned to the United States and settled in New York. He made no attempt to obtain practice, but spent his time in the dead-houses of Bellevue and the New York Hospital, and in working with the microscope.

During the same year he began to lecture on chemistry in the Medical School at Woodstock, Vt., giving his courses for two months in the spring, and lecturing twice a day. In 1841 he began to lecture in the same school on pathology, and continued to do so for thirteen years.

About the same time he began to lecture on pathology in the Medical School at Pittsfield, Mass., giving his lectures there in the autumn.

The remainder of each year he spent in New York, still working in the dead-house and with the microscope.

In 1847 he was appointed Lecturer on Physiology and Pathology in the College of Physicians and Surgeons, and during the same year was made one of the attending physicians of Bellevue Hospital.

It was in the year 1855 that the real work of his life began. It was at that time that he became the Professor of Pathology and the Practice of Medicine at the College of Physicians and Surgeons, and that he formally offered his services as a consulting physician.

He was already forty-eight years of age; twenty years since his graduation had been passed in preparation for the work of his life, and this preparation had been of a remarkably complete character. He was to be a teacher, and he had been practising teaching from the time that he was a sophomore at college; he was to be a consulting physician, and for twenty years he had been living in hospitals and dead-houses; he needed a liberal education for his work, and he had travelled over many countries and known many men and many books. The toil had been long and arduous, but when he fairly commenced his life-work his success was immediate and complete.

His practice and his teaching marked an era in the history of medicine in the United States. At a time when too many physicians were ignorant even of the gross lesions of the diseases which they treated; when the treatment of disease consisted too much in traditional remedies applied according to the shrewdness of the practitioner; when fresh air and sunlight were looked upon as enemies rather than friends—when young men without education, without experience, after hearing a few lectures, were called doctors and entrusted with the lives and happiness of their fellow-citizens—at a time when everything was hazy, indefinite, uncertain, there appeared a man in New York who actually knew his own business; a man who cared nothing for traditions, or theories, or arguments, but who for year after year had been storing up, in a most retentive memory, facts—facts about the symptoms, the course, and the lesions of disease—facts about the effect of remedies—not facts colored and misrepresented by the medium of theories, but the facts of the impartial observer.

What wonder was it that the advent of such a man was hailed with relief, that students crowded to his lectures, and that his consultation practice at once assumed large proportions.

For years the place that he held in New York was such as has been held by no other physician. He was not merely one of the most eminent physicians, he was the most eminent; his word was law, his decision was final.

In later years the profession grew up to its master, and even passed him by. His authority was no longer supreme. The scholars trained in his school cared as little as their master had done for any authority but that of nature; and with this came also the natural reaction, there was a certain relief from the overshadowing influence of a single man.

From the year 1855 on, Dr. Clark's life in New York was one devoted to consultation practice, to the hospital, and to the college. His consultation practice was very large. In 1861, when I was a student in his office, his consultation visits occupied not only a large part of the day, but the greater part of every evening also. A few years later than this he told me that his practice was even larger. I think that his work of this kind must have reached its greatest development about the year 1870.

As a physician Dr. Clark was precise, exact, and methodical. Every patient was examined with a technical skill which was conspicuous, with the intuition and judgment of the born physician, and the case was illuminated by a large previous experience, always ready for use from the stores of his memory. Either he recognized at once the nature of the disease, or he avowed his ignorance, or he was content to wait for time to make all things plain.

He was not an enthusiastic therapeutist, but the plans of treatment which commended themselves to his judgment were carried out with skill and courage.

In the positive treatment of disease, his especial achievements were the treatment of peritonitis by opium, and the enforcement of the value of fresh air in the continued fevers.

But his influence for good was also widely felt in the prevention of doubtful and injurious plans of treatment.

As a consultant he gave satisfaction both to patient and physician. To the patient, confidence was given by his noble presence and benignant aspect, while the physician rested in the full assurance that in no way would his influence and authority be impaired.

But it was as a teacher of medicine that his powers reached their full development; it had become a second nature to him to acquire information, to digest it, and to communicate it to others. Curiously enough, this was done largely without the aid of writing. He could trust his memory even for the minutest details, and his mind had acquired the faculty of arranging and presenting what he had to say in an orderly and clear manner. So he was a teacher by the spoken and not by the written word. Many generations of students have felt for the rest of their lives the stamp of his teaching, but to the present world he speaks no longer. His writings were few, and not to be compared to his lectures.

In 1875 his interest in his lectures began to flag, and there were, even then, some premonitions of the disease which later destroyed his life. It was at this time that he was made president of the college in which he had taught so long.

In 1882 he resigned his position as professor in the college, and with this ended his active life.

He still saw many patients, he continued to be president for two years longer, but he was no more the same man. A chronic inflammation of the cerebral arteries was gradually affecting the functions of his brain. A most distressing vertigo constantly annoyed him. All his mental faculties became slower, even his prodigious memory began to fail.

In December, 1884, came the first decided attack—partial aphasia and partial right hemiplegia. After this came other similar attacks, all referable to the same side of the brain. Then he became completely aphasic, and would sleep away a large part of each day. Finally, on September 13, 1887, came the end.

He was a man whom nature had made on a large scale—of large frame, of commanding presence, with vigorous health, with a large brain. It is always hard to tell of how much such men are really capable. There is often something sluggish about their mental processes, and it requires external stimulants to spur them on to their utmost development. It is to such men that the United States have more than once been indebted for their preservation. Imperturbable, patient, never discouraged, capable of extreme and continuous bodily and mental exertion, and yet modest, shunning publicity, reticent of speech. Such a man was Dr. Clark. Circumstances made him a physician, and he was the first physician of his country and time. But a larger and more arduous task would have found him equally ready.

In looking back over Dr. Clark's life it seems to me that, perhaps, one of its most useful results was the influence it exerted on the medical profession. Here was a man whom everyone knew, who had attained to the highest honors in the profession, and the largest success in practice, and yet no one could accuse him of a mean or an unworthy act—no man was his enemy. He shunned publicity and notoriety in every form; medical politics were unknown to him; he appeared but rarely in the medical societies or the journals; and yet everything came to him. He never tried to do anything but to learn all he could about the science and art of medicine, and to communicate this knowledge to others; and, behold, honors, practice, wealth, were added to him. How many a struggling and discouraged physician has looked at Dr. Clark and taken heart once more to walk in the narrow and straight way of integrity.

I cannot close without adding my own tribute to the dead.

Dr. Clark was my father's friend, and he was my friend. He was my teacher, my guide, my example. In severe illnesses he cared for me; in his own last sickness I watched the courage with which he saw death approaching. It fell to me to succeed him in the college chair which he rendered so illustrious; it has been a constant incentive to exertion that his successor should not be unworthy of him. He was my father in medicine, and, as a son, I mourn his loss and revere his memory.

Clinical Department.

ASEPTIC CASES FOR SURGICAL INSTRUMENTS.

By A. HOLMBOE, M.D.,

ASSISTANT SURGEON, DR. CHR. FENGER'S CLINIC, EMERGENCY HOSPITAL, CHICAGO, ILL.

The ideal of modern surgery is perfect asepsis. The principles to be followed to reach that end are at present well established. Our method of carrying out these principles, however, is as yet very far from the ideal. When our method is perfect, our asepsis, as far as it rests with the surgeon, will also be perfect. Every detail, therefore, is important. We are to-day disinfecting everything and everybody, so to speak; the only part of our *armamentarium* so far neglected being instrument-cases of various descriptions, pocket cases, and instrument-bags. It is, *a priori*, evident that our old-fashioned appliances must necessarily become more or less infected, and act as veritable germ-carriers; the material used in their construction making disinfection impossible. To prove the correctness of this assertion, the following experiments, suggested by Dr. Fenger, were made. Two of Dr. Fenger's instrument-satchels were used, viz., (A) physician's instrument-bag in active service about two years, and (B) canvas bag (carpenter's bag) used for about three months, never in particularly septic cases, and looked upon as our absolutely "clean" bag.

Exp. 1.—Two smooth, polished scalpels, metal handles (all our instruments are provided with metal handles), were sterilized. One (*a*) was put in satchel A, and the latter was wrapped up in an antiseptic dressing to avoid air-infection. The other scalpel (*b*), which may be called the control-scalpel, was immersed in a gelatin-culture fluid.

Scalpel *a* was removed after six hours and also immersed in the gelatin fluid. Omitting the technical details, we will simply state the results here: Control-scalpel (*b*), negative result. Satchel-scalpel (*a*), after twenty-four hours, gelatin turbid, numerous colonies; after forty-eight hours, the entire gelatin mass was liquefied.

Exp. 2.—Two sterilized scalpels: One scalpel (*a*) put in satchel B; one (*b*) control-scalpel.

Control-scalpel, negative result. Satchel-scalpel (*a*), after six hours' contact with satchel B (the same precautions having been taken as in Experiment 1), after twenty-four hours, gelatin clear; forty-eight hours, gelatin turbid; fourth day, liquefaction.

Further experiments are in progress, but are not yet finished.

These experiments showed forcibly that our vehicles for carrying instruments were unsafe, because they could not be disinfected. It therefore became necessary to replace the old instrument-bags, etc., by new ones that could be disinfected by boiling, in five per cent. carbolic-acid solution, for instance. To that end the following outfit was devised, and is now in use in Dr. Fenger's hospital as well as in private practice.

1. *Instrument-towels.*—These are ordinary linen towels with a strip of the same material sewed on to form pockets for the instruments. These towels were devised about a year ago by Dr. Fenger's former assistant, Dr. Bayard Holmes, of this city. I should, perhaps, mention that the instruments, when not in use, are kept on glass shelves which are washed with five per cent. carbolic-acid solution once a week. All instruments are boiled for one hour in a similar solution once or twice a week. Instead of one old-fashioned pocket-case, six new ones were made of light canvas, with flaps to fold over the instruments, and a tape on the outside to keep it closed. The instruments are kept in position by tape-loops on the inside of the canvas.

To replace our old instrument-bags, one dozen new ones were made. They are simply bags provided with handles and straps of the same material (no leather, buckles, nor locks are used); the straps are to be knotted. A piece of hard-wood, one-fourth of an inch thick, is used to form a bottom to the bag. By keeping a large number on hand, a fresh one can be used every day, if desired.

The above designs recommend themselves to general use by enabling us to keep our instruments in, so to speak, aseptic surroundings, inasmuch as the towels, pocket-cases, and instrument-bags can, without injury, be thoroughly disinfected by boiling, thereby avoiding the danger of infection from one source, at least. They are cheap; anybody can make them; and the cost of the material needed for the whole outfit is trifling.

Progress of Medical Science.

Actinomycosis in a Woman.—Dr. Hoeffner has described the following case: A woman, aged sixty, suffered in November, 1884, and January, 1885, with pains in the right loin resembling renal colic (*The British Medical Journal*). Each attack was followed by urticaria and diabetes insipidus. In April, 1885, the attacks grew longer and more frequent; much muco-pus was passed with the urine, and there was great pain and tenderness in region of the right kidney. In November the attacks recurred, but this time resembled gall-stone colic; the pain radiated from the liver to the right shoulder. In January, 1886, a swelling resembling an abscess formed in the right hypochondrium, and was opened by Professor Boeckel in February. Instead of pus, serum with fungous tissue came away; it was sprinkled with grass-green bodies, the size of a grain of wheat. No communication could be found between the incised structure and the abdominal cavity. The wound was scraped, disinfected, and dressed with iodoform gauze. The green bodies were examined, and found to be actinomycetes. The wound slowly became cleaner; its edges remained red and indurated, and not very tender. The scanty pus which exuded was mixed with the bright green bodies. There were indurated tracts in the neighborhood; no antiseptics produced any effect. At this stage the general condition was good; the urine contained muco-pus, but the fungus could not be found in it. The wound at length became a fistulous track. In June, 1886, pleuritic effusion set in in the right side of the thorax inferiorly, with rise of temperature. On June 27th, fits of coughing brought up fetid muco-pus. In August the patient became very ill with ascites, anasarca, jaundice, and a bed-sore, yet she got stronger again till spring, 1887. An abscess then formed to the inner side of the right scapula. On incision, thick pus and actinomycetes escaped in quantities; a fistulous track was left, which, alternately with the track in the right hypochondrium, discharged the parasite. The former track on one occasion communicated with the pulmonary fistula, then the green bodies were found in the sputa; they were not so green as those escaping from the other cavities. The patient died of exhaustion on July 30, 1887. The disease thus lasted for two years and a half. A large abscess was found in the right lobe of the liver, involving adjacent viscera. It was full of the fungus; it communicated with the lumbar fistula, which was itself in communication, under a wide area of upheaved subcutaneous and muscular tissue, with the fistula in the thorax. The right suprarenal capsule adherent to the liver was infected with the fungus, but the kidney, including its capsule, was free from infection, though congested. The diaphragm and other organs were healthy. The fungus appeared to have begun its ravages from the right transverse colon, where it touches the liver. The fungus had migrated toward the surface, through the thoracic parietes, forming the first abscess; then it had made its way between the skin and the muscles toward the scapula, perforated an intercostal space, and finally entered the lung. The green coloration of the fungus appears to be peculiar to cases where the abscess is hepatic; in other cases the masses were white or yellow, and even in this patient those which were coughed up from the lung were much less green than those in the hepatic abscess.

How to Prevent the Spread of Infection.—An English health officer has formulated the following suggestions: It is supposed that a case has developed in a family, and that the patient is not to be removed from his home. The first requisite is to prepare a room in which the patient may be isolated. It should be cleared of all furniture which is not absolutely required, and the floor should be cleansed and left bare. The room should be regarded as a source of danger, and should be cut off from the rest of the house by means of a sheet, or sheets, wrung out with a disinfectant solution and kept moist therewith, suspended outside each door, and reaching to the floor. Everything taken into that room should be regarded as infected, and nothing should be removed without disinfection. Towels, pocket-handkerchiefs, soiled linen, etc., used in the room, should be boiled in a disinfectant solution. The patient should be washed with a disinfectant solution and soap and water, and in scarlet fever the body should be anointed with oil. An open fire should be kept in the room (winter and summer), and if no ventilation is provided in the house-construction, a window should always be left open a little. Dogs, cats, and other pets should be excluded from the room, as they carry infection readily. In case the patient should be so unfortunate as to die, the body should at once be swathed in disinfectant cloths, and should be sealed in a metal coffin before being removed from the room. When the room is no longer required by the patient it should be thoroughly disinfected. It should then be left open, to air thoroughly for a week. All its contents should then be washed, and all suspected articles, such as toys, should be burned.—*The Sanitary News*, December 24, 1887.

The Diagnosis of Medullary Cancer.—The subject of cancer is always before the profession. In a recent paper on the symptoms, diagnosis, prognosis, and treatment of the medullary variety of carcinoma (*The Philadelphia Medical Times*, December 1, 1887), Dr. Hyde, of Cortland, N. Y., summarizes his views on diagnosis as follows: Medullary cancer appears in early child-life, and rarely in patients over sixty years of age. Hard or scirrhous cancer is never seen in persons under twenty years of age, and rarely as early as twenty-five years of age. Medullary tumors never have the stone-like hardness of the scirrhous cancer, nor its irregular and jagged outline. The medullary, unlike the scirrhous, is highly vascular, develops rapidly, maturing in nearly half the time of the hard cancer. Persons with soft cancer do not show the cachexy so early as in the hard; it appears suddenly at the time when its diseases or degenerations are manifest, and then becomes strongly marked. The medullary, as a rule, grows more rapidly than the sarcoma, is much more vascular than the latter, its boundaries less distinct. Sarcoma is scarcely known in childhood. The medullary growths can be distinguished from the inflammatory swellings by the entire absence of the symptoms and signs of the latter during their normal life. None of the innocent tumors have so marked a preference for special localities and textures as the soft cancer. The most reliable diagnostic sign of medullary cancer is its marked elasticity, not so plainly detected in its earliest growth as a little later, when it enlarges more rapidly. As soon as the growth becomes developed sufficiently to become the subject of surgical opinion, in a large majority of the cases the elasticity can be detected.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, February 4, 1888.

THE TRANSMISSION OF INFECTIOUS DISEASES THROUGH THE MEDIUM OF RAGS.

DURING the summer of 1886, the State Board of Health of Massachusetts requested Dr. C. F. Withington to undertake an investigation of this subject, which has lately received so much attention from physicians and sanitarians. Opinions are still considerably divided as to the true state of affairs, and it appears from Dr. Withington's elaborate report ("Eighteenth Annual Report of the State Board of Health of Massachusetts," Boston, 1887) that reliable facts are difficult to obtain. We are told at the outset that it was by no means easy to collect original data, owing to the length of time that has elapsed since the general prevalence of small-pox and cholera in the State of Massachusetts.

Again, "information as to the transmission of the other acute infectious diseases, including measles and scarlet fever, is lamentably imperfect, owing to the almost constant prevalence of such diseases in manufacturing towns, so that opportunities for infection are always present. It is also doubtless true that a majority of rag-operatives have already had these diseases in their youth, and thus acquired immunity against any infection which the rags might carry."

Nevertheless, the author, by means of painstaking personal investigations, including inquiries through physicians, manufacturers, and hospitals, was able to collect a large amount of information.

It is, of course, impossible here to follow Dr. Withington in a detailed examination of the mass of evidence thus brought together. But for the information of our readers we reproduce his conclusions, which are as follows:

1. Small-pox has been transmitted through the medium of rags in a certain number of cases, small in proportion to the whole number of persons who handle rags, but absolutely numerous enough to show that unvaccinated workers in rags are exposed to an actual, if not imminent, danger of infection from this source.

2. The source of this infection is more frequently domestic than foreign rags, though the disease has been caused by the latter. This possibility of infection through imported rags accords with what is known of the tenacity of life of the variolous poison.

3. Among the rarer means whereby cholera is transmitted are textile fabrics infected with choleraic discharges. There is evidence that clothing from cholera patients, and possibly clothing merely packed in an infected locality, has, when transported to a distance and there unpacked, caused the disease in those who have handled it, thus starting a fresh cholera focus. A proper distinction exists between clothing, on the one hand, recently removed from the body and again, not long after, be put on to the body; and rags, on the other hand, which, if transported to this country, are certain to have undergone a carefully discriminative sorting and drying, and to have spent a considerable time in warehouse and on shipboard.

4. The statement that cholera has been transmitted by paper-rags rests upon a solitary case, of which the details are not complete, and on the reliability of which some of the highest authorities on cholera have cast doubt. If the case be accepted, it is one of infection by *domestic* rags, carried only fifty miles from their place of collection.

5. An epidemic affection, known as "rag-sorters' disease," appears to have broken out on three or four occasions in European paper-mills. It was probably, though not certainly, the disease called anthrax.

6. Authenticated instances are not to be found in which the other infectious diseases—typhus and typhoid fevers, scarlet fever, measles, and diphtheria—have been transmitted through rags; though it is to be said that such evidence, supposing the fact to exist, would be very difficult to get. Neither do the mortality tables, as shown by registration reports, show a preponderance of deaths from these diseases in the paper-making towns.

7. There is no evidence to show that rag-sorters as a class are, except for occasional cases of small-pox and a certain amount of pulmonary irritation from the dust of improperly ventilated rooms, less healthy than other persons engaged in in-door manual occupations.

8. Despite the fact that cholera is not known to have ever been conveyed to this or any other country in foreign-baled rags, it is a reasonable precaution to prohibit the landing in any United States port of rags gathered in epidemically infected localities, in view of the possibility that among such rags there may have been thrown articles of infected clothing which have not been sufficiently dried and aired, or have not occupied enough time in their transportation to be devoid of danger. Such prohibitions should be limited to the time and place of epidemic infection; but all necessary precautions should be taken to make sure that rags shipped from a healthy port were not gathered or baled in an infected place.

9. As the only safeguard against the occurrence of small-pox among operatives, paper-mill owners, whether "incorporated companies" within the purview of the statute or not, should make evidence of successful vaccination an absolute prerequisite to the employment of any person in the mill, and a revaccination at regular intervals (not merely on the occurrence of an epidemic in the neighborhood) a condition of being retained in their employ.

10. As the contagion of small-pox, phthisis, and perhaps other diseases, is capable of being inspired when the particles carrying it are suspended in the air in the form of dust, and as dust, even when it carries no contagion, is irritating to the respiratory passages, every mill should have, in connection with each table in the

rag-room and in the dusting-room, a ventilating system, preferably consisting of flues connected with an exhaust-fan, so that the dust, as fast as it is disengaged, may be withdrawn from the air. The success which attends the working of such an apparatus, in some mills where it is in use, is a sufficient warrant for its general introduction.

11. A law similar to that of Great Britain (Section 125 of the Public Health Act of 1875), imposing a penalty on the selling or giving away of infected rags from persons sick with any dangerous disease, seems desirable. Public institutions and private householders should be obliged (and not, as at present, simply advised) to insure the disinfection of the more valuable articles and the destruction by fire of all rags that have been thus exposed.

12. As domestic rags comprise more than half those used, and represent a still larger proportion of the infection likely to be carried, it follows that they should participate in whatever disinfection is thought necessary. This fact points to the paper-mill as the proper place for making such disinfection. The sulphur process would doubtless afford the least embarrassment to the manufacturer; the bales being opened in a tightly closed room, the rags being spread on racks, and sulphur burned in the proportion of two pounds to each one thousand cubic feet of space. The introduction of steam under pressure, the rags being similarly disposed, would be the most effective disinfection possible, but would dampen the rags to their injury, unless the moisture were dried out at once with a current of hot air.

TURPENTINE IN DIPHTHERIA.

We have, on several occasions, referred to the use of turpentine in diphtheria. Recommended originally in Germany, and claimed to be almost a specific, it was there, also, that the employment of the drug was subjected to the most severe criticism. Some recent publications have again drawn attention to the alleged value of this substance, and most remarkable among these is an article by Dr. Roese, which appeared in the *Therapeutische Monatshefte.* The author asserts that he has employed turpentine in diphtheria for the past four years. In that time he lost only five cases out of sixty that came under treatment. Two of the fatal cases concerned infants one year old, who appeared moribund when first seen, and died a few hours later. The other fatal cases were also unusually severe from the start, two dying in thirty-six hours, and one surviving five days. This is certainly a noteworthy record, as diphtheria statistics go.

The oil of turpentine was administered in drachm-doses, three times a day. Sweet spirits of nitre was used as a corrective, in the proportion of one part of the spirits to fifteen of the turpentine. Symptoms of intoxication were never observed by the author. In addition to the turpentine, a two per cent. solution of sodium salicylate was given every two hours, in tablespoonful doses. A gargle of chlorate of potash solution was likewise employed whenever possible. Under this plan of treatment rapid amelioration of local signs and constitutional symptoms was observed. Usually improvement began at once, and it was rarely necessary to push the drug beyond five or eight doses. It should be remarked in this connection, however, that a very generous and stimulating fluid diet (strong broth, port wine, milk, etc.) formed a feature of Dr. Roese's plan of treatment.

Those who are inclined to be sceptical with regard to the utility of medicines in the severer forms of diphtheria (and the profession contains many such) will scarcely accept the author's figures without challenge. On the other hand, for the very reason that violent diphtheria ordinarily justifies so gloomy a prognosis, we are ever ready to employ any means at our command which may possibly reduce its frightful mortality. There is no reason, therefore, why the turpentine treatment of this disease should not be given a fair trial.

SUPRAPUBIC PROSTATECTOMY.

The surgery of to-day is nothing if not aggressive. Not a single structure can be said to be so cryptically bestowed within our economy that the pushing blade of the operator will not some day expose it to the light of day. The newly proposed operation of prostatectomy may be taken as an illustration of these statements. In those frequent disorders of advancing years depending upon prostatic enlargement, physicians have, until recently, been content to resort to such palliation as the skilful use of the catheter, or the exhibition of drugs, could afford. Now, however, several operative procedures are already clamoring for professional recognition. The most recent measure of this kind is suprapubic prostatectomy, the more general employment of which was advocated by Mr. McGill, at a recent meeting of the London Clinical Society. The author related three cases in which the operation had been successfully performed (*The British Medical Journal*, November 19, 1887).

The operation itself consists in opening the bladder above the pubes in the usual manner, and removing with scissors and forceps that portion of an enlarged prostate which prevents the outflow of urine.

Case I. had suffered from urinary symptoms for seven years, and had not been able to pass urine without a catheter for seven months. Six calculi, weighing one hundred and seventy-four grains, and a portion of prostate as large as a walnut, were removed by suprapubic incision. The patient made a speedy recovery, and did not require the use of a catheter.

Case II.—Symptoms of prostatic enlargement for two years; acute symptoms for a fortnight, fetid urine, and frequent micturition. He was treated for three weeks by ordinary methods, without benefit. The middle lobe of the prostate, the size of a bean, was removed, with immediate benefit. He left the hospital on the twenty-seventh day, with the wound healed, and passing water without difficulty.

Case III.—Prostatic symptoms for six years; acute symptoms of more or less severity for three years. On admission into the hospital he was found to be extremely ill. He vomited all his food, had constant diarrhœa, and passed putrid urine, which deposited one-third of its bulk of pus. On opening the bladder, the ureters were felt to be much dilated. The projecting portion, the enlarged prostate, was removed. He made a quick and satisfactory recovery, and was able to micturate without difficulty.

According to McGill, the benefits derived from the operation were of two kinds: First, acute symptoms were relieved by the drainage of the bladder; and, secondly, the cause of these symptoms was removed by excision of a portion of the enlarged prostate. As yet the operation had only been practised in acute and urgent cases, but it was not improbable that in the future it might be resorted to before any acute symptoms supervened.

Of course, these cases are not sufficient to justify generalizations, and a much wider experience is necessary to teach us whether this new departure constitutes a real advance, or should be regarded merely as an innovation. Possibly it will yet appear that the principal route is, after all, safer than the suprapubic method of attacking the prostate.

THE MEDICO-LEGAL ASPECT OF PROHIBITION.

To anyone who reads the signs of the times, it must be evident that the next social question to be decided is that of intemperance. In the political world we hear less, it is true, about it than about the tariff, but the latter is a purely political issue. The thinking men of the country are divided upon it. The temperance question, however, though it may have to be settled by political measures, is not, strictly speaking, a political, but rather a social, matter. It appeals to every home, even to every individual.

In some of our States the matter has been brought directly home to individual communities. In our own State the first guns are now being fired. We do not know how long it may be before public sentiment will crystallize upon some plan of operation. One of our exchanges, the *California Journal*, contains a well-written article, in which the writer thus forcibly puts his case: "The proposition is this: Has a man a right to be a drunkard? . . . Has a man the right to have children to inherit his weakness; has he the right to transmit such tendencies to the unborn?" The belief is expressed that we shall soon consider drunkenness, inebriety, dipsomania, or whatever names we may give to excessive drinking, as a disease, just as we now regard insanity. Society claims and exercises the right to protect itself against the latter, and shuts the victim up in a proper place. It will in a similar way come to recognize its right and duty with reference to the victim of intemperance. He will be treated, in other words, as if he were insane.

This is rather advanced doctrine, and yet, as is suggested, the trend of thought in these days is all that way. The view taken is a medium one between the philanthropic and the legal. The former would regard all vice and crime as the result of inherited tendencies, and, to a great extent, excusable. The latter places drunkenness in the category of crimes brought about by the person himself, and therefore deserving of punishment. Public sentiment is not entirely in favor of either of these views. Some strongly denounce every victim of strong drink, have no sympathy for him, and would treat him as a lawbreaker. A very few recognize the fact of inherited tendencies, and occasionally their compassion assumes rather a maudlin type.

Prohibition, at least the open manufacture and unrestricted sale of liquors, will undoubtedly come in time, but we shall get to it by degrees. In the meantime certain temporary measures may have to be adopted, all looking toward the great end. Practical attempts are even now being made to solve the problem. It would be an easy solution of certain aggravated phases of it to apply the same medico-legal principle to inebriety as to insanity. It is true that drunkards are now shut up, but it is in prison, and the confinement is regarded as a punishment for an offence, and not as a means for preventing a mentally unsound person from preying upon the community or begetting children, who, when conceived in drunkenness, "have a tendency to crime and moral irresponsibility." It may be said that we could not provide accommodations enough. In reply, it can be safely alleged that there will simply be a transfer from prison to asylum. It is a well-known fact that drunkenness is the exciting cause of most capital crimes, and if intemperate men are confined early enough, much crime would thereby be prevented.

THE MEDICAL FUTURE OF THE NEGRO RACE.

A QUARTER of a century ago it was supposed that the negro problem had been completely worked out. The emancipation proclamation was regarded as a sort of Magna Charta for those just relieved from slavery. Twenty-five years have taught the politicians that their work has by no means ended, and these years have brought to the consideration of the medical profession many questions of a medical import just as interesting, and perhaps more important, as those of a strictly political nature.

Last spring, during the college-commencement season, we published an article on the exercises occurring at one of the Southern medical institutions exclusively for colored men. The evidences of progress there being made seemed to us gratifying, and we commented favorably upon them. We then expressed the idea that the medical history of the negro race could be worked out and tabulated only by those of the same race, and we see no reason to alter our opinion. The comparatively new departure seemed to us a distinct step forward.

This is a question which primarily concerns our Southern brethren, and yet is one of general interest. In view of the far-reaching consequences, we may say it is one of universal concern, if not to us, at least to the next generation. Change of environment always induces corresponding changes in the physique, mental traits, and morals of any man, or group, or even nation of men. No more striking example of this can be shown than in the changes which have occurred in the negroes since the war, to the results of which they may mostly be ascribed. For example, before the war they were much less susceptible to malarial influences than the whites, but now this difference has been nearly, if not quite, effaced. Concerning other diseases, a similar, if not quite so marked, state of affairs prevails.

We have been inclined to take, all along, an optimistic view of the matter. We observe that some of the Southern journals are not so hopeful. Their opinions deserve the most careful consideration. They are nearer the actual dangers, if such there be, than are we of the North. We cannot believe that their statements are colored by prejudice. They are too careful and scientific observers to be swayed by any such motive. One of the latest issues of *The American Practitioner and News* (Louisville, Ky.) contains some very pertinent remarks on the subject. It calls attention to the rapid birth-rate among the negroes for the decade ending in 1880, but does not believe that the next census will show for the succeeding ten years a similar ratio. Among the influences at work against a continued increase it notes the migration to cities, where the conditions of life are always unfavorable to rapid increase. It declares that the death rate of the blacks is very far above that of the whites, and that tubercular disease is decidedly on the increase. "City life," it says, "must be doubly unfavorable to the blacks. Few of them are skilled laborers, or have either the opportunities or disposition to become so. They must, therefore, when they labor at all, perform labor that commands the lowest wages, and, as a consequence, their living must be of the poorest character, and they must content themselves with the most inferior lodgings. Education does not and will not help them; it simply causes them to despise and neglect such employment as they can now get, while no avenue opens to them for better. This is notably the case with the females. It unfits them for the position of servants, and creates wants that cannot be satisfied by the earnings of the manual labor of any husband they can command. As a consequence, a very large proportion of them choose to earn what they can by lives of prostitution."

However, it looks at both sides of the question, and adds that "a certain proportion of the negro race have the stamina, the staying qualities, and the ambition to enable them to sustain themselves even alongside the average Anglo-Saxon, and as the centuries pass on, and the worthless classes that do so much to degrade the race are weeded out by disease, they will continue to come into a better position as useful and respected citizens." The question, therefore, resolves itself into this, Is there leaven enough to leaven the whole mass? We believe there is. Habits of life most definitely determine susceptibility or non-susceptibility to disease. Time must be allowed a race to subject itself to new conditions. The pendulum swings slowly, and perhaps has gone to an extreme, but it will adjust itself in time. Twenty-five years cannot undo the race peculiarities which were four hundred years in moulding. With us, the negro problem can never be what it is in the South, even from a strictly medical point of view. But we believe that another quarter of a century will show a physical progress of the negro population commensurate with the material.

PROGRESS IN MEDICAL EDUCATION IN THE UNITED STATES.

The report of the Illinois State Board of Health for 1887, of which we have recently received a summary, contains, as usual, some interesting facts.

With regard to medical colleges, there have been since 1886 two new regular schools established, while two eclectic schools have lapsed into innocuous desuetude.

As to medical students, it appears that since 1882–83 there has been a gradual decrease in the number of homœopaths from 1,204 to 1,070, while the students in regular schools, though fewer in number during 1884, 1885, and 1886, were in 1887 in excess of the numbers in any previous year, being 10,137, as against 10,075 in 1881–82. The decrease of irregular graduates in New York State has been from 113 in 1881–82, to 73 in 1886–87.

The standard of medical education shows continued signs of improvement. The report shows that there are now 114 colleges which exact an educational requirement of intending matriculates, as against 45 formerly—there being no change in this respect from the previous year; that 43 colleges now exact attendance upon three or more courses of lectures, as against 22 formerly—being a gain of two over 1886—and 57 others make provision for a three or four years' graded course; that hygiene is now taught in 114, and medical jurisprudence in 112, colleges, as against 42 and 61, respectively, prior to 1883. There is an increase in the average of lecture-terms from 23.5 weeks to 24.9 weeks during this period, and 114 colleges now have terms of five months or over, and 63 have terms of six months or over, as compared with 101 and 42, respectively. There is only one medical college that has a course less than twenty weeks, the Medical College of Georgia.

The effect of a higher standard of qualifications for graduation is further shown in the diminishing percentage of graduates to the total number of students. In 1882–83, out of every 1,000 matriculates 322 were graduated, taking both the United States and Canada and all schools of practice into the account. In 1886–87 only 294 out of every 1,000 matriculates were graduated. In the United States alone, in 1882–83, out of every 1,000 matriculates 331 were graduated, while in 1886–87 only 305 out of every 1,000 matriculates were graduated.

REGULAR MEDICINE AND THE MIND-CURE.

The Rev. Heber Newton, in a recent lecture on the mind-cure, gives the medical profession some rather superfluous advice. This is what he says:

"The 'ism' [of Christian science] is one among the many signs of the inevitable reaction from the ultra-materialism of our age of physical science. It gives us the clue to the interpretation of the miracles of Christ in the higher naturalism which seems to us a supernaturalism. Such a man must have been a walking battery of electricity. Our medical faculty, if wise, will not attempt to sneer down a curative force which they have always theoretically admitted, but which they have practically neglected. Rather will they correct the defective methods of a too purely physical science by the supplementary methods of mental science. Let them absorb what is good in this heresy, and thus they will best refute it. Let them enter in their pharmacopœia the tonics of thought and feeling. Let them administer mental and moral stimulants scientifically, as those who really believe that an idea may be the most potent of drugs."

This is all very well, and it has been said over and over again for a good many years. Very few physicians fail to learn early in their career the curative power of hope. But conscientious physicians cannot do what

Christian "scientists" do, give promise of cure to persons whom they know positively can never recover. Their faith-curing powers are limited by their honesty and their knowledge; and this must always be the case. Quacks, who are probably ignorant, and certainly dishonest, can use these powers of faith to an unlimited success. And this explains, as everyone knows, why the quack sometimes succeeds for a time with a case in which regular medicine has failed. But, on the whole, it is better for the world and society that truth, wisdom, and knowledge be our guides. And so rational medicine repudiates faith-cures as pernicious in the methods, and eventually harmful in their influence.

THE TEMPERATURE OF OUR FOOD AND DRINKS.

Of all nations the American is most in the habit of taking his food and drink at a temperature as remote as possible from that of the body. Ice-water drinking is a national habit, and ice-cream is a national dish, predilection for which runs through all classes of society, and becomes a binding force in social, and, we might add, scientific and religious gatherings. Americans should, therefore, take an interest in the experimental researches on the temperature of our food and drink made by certain foreign savants whose names are, as is usual, hyperplasic with consonants just in proportion to the rigidity of their science and the seriousness of their inquiries.

The temperature of our food and drinks was treated of by Von Späth and Kostjurin a year ago (*Münchener Medic. Wochenschr.*, 1886, p. 533), and more recently by Uffelmann, of Rostock (*Ibid.*, 1887, p. 999).

Professor Uffelmann reviews the work of his predecessors, and draws his conclusions partly from this, and partly from his own experiments. They bear first upon the temperature of ingesta in health, and the rules laid down are:

1. That, in general, a temperature of food and drink which approaches that of the blood is most healthful. For nurslings such temperature is essential.

2. For quenching the thirst, the best temperature is from 50° F. to 68° F. The favorite American temperature is, as is well known, 32° F., and an issue is raised at once between Professor Uffelmann and the American nation.

3. The ingestion of very hot or very cold food or drink in health has a damaging effect, which is increased just in proportion to the rapidity with which the hot or cold substance is taken. Hence the gulping down of ice-water or hot coffee, etc., means eventually, according to the light we are quoting, a mere ventral damnation. If a person takes a drink for the purpose of warming himself, as in cold weather, he can accomplish this by having the drink at a temperature of 116° to 120° F.

4. The use of very hot and cold substances, following or alternating, is injurious to the teeth. But the taking of cold water lessens the injurious action of extremely hot substances upon the stomach.

5. Ingestion of cold food and drinks lessens the bodily temperature, whether it be normal or febrile.

6. Cold fluids lessen the hyperirritability of the stomach.

Cold ingesta raise the tone of the stomach, increase peristalsis, and promote movement of the bowels. Cold food and drinks increase the tendency to cough, according to Uffelmann, by causing reflexly a congestion of the bronchial vessels. Hence, persons with bronchial disease ought not to indulge in cold drinks. It is, however, a common custom to give persons who suffer from pulmonary hemorrhage ice to swallow; and, according to the view stated, this would be an injurious practice.

Hot food and drinks stimulate the stomach more than cold. But after repeated use they lessen the tonus of the digestive tract, and cause congestion and dyspepsia. This condition has been observed after the so-called hot-water cure. Hot drinks tend to lessen bronchial irritation, and this is one cause, possibly, of the success in some cases of the hot-water treatment of consumption.

News of the Week.

Dr. B. Farquhar Curtis has been appointed Attending Surgeon to the St. Luke's Hospital, vice Dr. George A. Peters, resigned. We congratulate Dr. Curtis on this well-deserved honor.

The One-term Service in the New York Hospital.—The Governors of the New York Hospital at their last meeting voted against the one-term service. This action creates one vacancy in the medical, and one in the surgical, staff of the hospital, which will shortly be filled. Several candidates have already been named.

Dr. Albert Strang, aged forty-five, who lived at Yorktown, Westchester County, was brought to Bellevue Hospital, last week, suffering from dementia. He died at the hospital later from pneumonia. Dr. Strang was graduated from the Bellevue Hospital Medical College in 1867, and for two years subsequent was house surgeon at Bellevue Hospital.

The Latest Remedies for Sea-sickness are antipyrin in doses of gr. xxx. to gr. xlv. (Dupuy), and resorcin in doses of gr. xij. to gr. xxij. (J. Andeer).

Dr. H. Augustus Wilson has been elected Professor of General and Orthopedic Surgery in the Philadelphia Polyclinic and College for Graduates in Medicine.

New Insane Asylum at Ogdensburg.—The New York Assembly has passed a bill appropriating $328,700 for the new State insane asylum at Ogdensburg.

The Receipts of the Health Officer of this Port for 1886 were $51,298, and the disbursements $21,332.14. The figures for 1887 were about the same.

"Who shall decide when doctors disagree," was originally said of casuists, not of medical men.

Benzoate of Soda in Uræmia.—Starting from Cohnheim's theory of uræmia, and from the fact that benzoate of soda inhibits the formation of urea within the system, Dr. A. S. Partzevsky, of the Basmannaia Infirmary for Laborers, in Moscow, administered benzoate of soda (*Meditzinskoiè Obozreniè*, No. 5, 1887, p. 508) (*British Medical Journal*) in ten cases of uræmia, in seven of which the patients were suffering from parenchymatous, and in three from interstitial, nephritis. The drug was given every hour, in daily doses varying between one and two drachms. It was given either in a solution or in wafers, in capsules, and, where the internal administration was impossible, in enemata. Nine patients recovered, one died. Analysis of the cases has led Dr. Partzevsky to the conclusion that benzoate of soda cuts short uræmic attacks, the convulsive phenomena gradually disappearing and giving place to a deep sleep. The latter, in "a majority of cases, terminates by passing into full consciousness." Given on the first appearance of symptoms (headache, sickness, dilatation of pupils), the salt may prevent any further development of the fit. Albuminuria mostly disappears altogether. While this drug may be useful in uræmia, it is safe to say that any therapeutic procedure based on the theory that uræmia is caused by deficient excretion of urea will not prove successful.

A FIRE IN THE HOSPITAL FOR THE RUPTURED AND CRIPPLED.—On Sunday evening last, a fire occurred in this hospital, jeopardizing the lives of all the young crippled inmates. By the timely assistance of the medical staff the fire was soon controlled, and all the patients safely removed to an adjoining hotel. The damage to the building was very slight.

A SHOCKING ACCIDENT AT ROOSEVELT HOSPITAL.—A patient upon whom a trivial operation had been performed on Wednesday last, was taken to the elevator to be transferred to his ward. The orderly in charge not making sure that the elevator was in place, slid the stretcher containing the patient down the shaft, a distance of twenty-five feet. Death resulted a few hours afterward. The patient was recovering from etherization at the time the accident occurred.

MADE TO TESTIFY AGAINST A DEAD CRIMINAL.—Dr. Stewart, of Detroit, was compelled by the Court to state when, where, and for what he had treated a dead criminal. The prosecuting attorney was peremptory in demanding an answer from the witness. He said that the law did not recognize medical ethics to the extent of concealment of crime, and Dr. Stewart was bound to tell when, where, and for what he attended the dead man; but if the man were alive he need not tell what the man said if what he said would criminate him; but the man being dead, it was the doctor's duty to aid the cause of justice by telling all that passed between himself and the burglar. While there might be no objection to stating when and where a patient was treated, no physician should be compelled to testify as to what passed between the patient and himself, even after the patient was dead. Dr. Stewart's protest was eminently proper.

THE TINCTURE OF NUX VOMICA TRITURATES, each containing one minim, have proved very useful in the treatment of obstinate constipation, rapidly cleaning the furred tongue, and producing a copious action of the bowels. The tablets are also useful in dyspepsia and in the vomiting of pregnancy.—*Murrell.*

THE QUEEN'S WOMEN'S JUBILEE OFFERING, or its surplus, is to be devoted to the establishment of an institution for promoting the education and maintenance of nurses for the sick poor in their homes. The work is to be done in connection with St. Katherine's Hospital, an institution founded in 1148. We have not a queen, or a jubilee in this country, but a similar work to that indicated above has been inaugurated in this city.

THE LATE DR. WESLEY M. CARPENTER.—The Committee appointed by the New York Pathological Society to draw up resolutions upon the death of the late Secretary, Dr. Wesley M. Carpenter, presented the following, which was unanimously approved.

Whereas, it has pleased an overruling Providence to remove suddenly our honored Secretary, Dr. Wesley M. Carpenter; therefore be it

Resolved, That this Society has lost in him not only one of its most honored and gifted members, but an officer whose long, conscientious, and skilled services in its behalf have been largely and gratefully appreciated, not only by the members, but by readers of its Transactions everywhere;

Resolved, That his faithfulness and rare excellence in the performance of his responsible duties have been, and ever shall be, examples worthy of emulation by his sorrowing survivors. He taught emphatically that the best incentives for good work are a high sense of honor and a pure love of science;

Resolved, That in the death of Dr. Carpenter the members of this Society have lost a personal director and friend whose watchful care, sound judgment, and facile pen were ever ready in their behalf, and whose strict fairness and unusual correctness in reporting and guiding the proceedings of this body were never questioned;

Resolved, That while working modestly, earnestly, and successfully for the best interests of this Society, he was unconsciously, but surely, making for himself an enduring reputation as an accurate, accomplished, and classical medical writer. He not only spoke through and for others with a terseness and force which made his reports models of their kind, but often for himself with an originality and perspicuity which added greatly to the value of our records.

Resolved, That we also tender to his household and kinship our sincere sympathy for the loss of one who was taken from them and from us in the fullest tide of his extended usefulness, and join sorrowfully, though scarcely yet resignedly, with them in forced submission to the inevitable decree which comes sooner or later to all of us, but which came seemingly too early to him.

GEORGE F. SHRADY, M.D.,
JOHN C. PETERS, M.D.,
JOHN H. HINTON, M.D.,
Committee.

WALTER MENDELSON, M.D., *Secretary.*

THE CRAZE FOR ANTISEPTICS, says *The Medical Press*, still continues, though in a modified form; physicians and surgeons are still found going round with soap-flakes of various medications, showing that certain fashions die slowly. Among the most recent of these protective soaps is one containing three per cent. of biniodide of mercury, the present fashionable antiseptic. Gentlemen who still believe that medicine may be followed as a mechanical occupation, in which the scrubbing-brush, with malodorous drugs, replaces brains and experience, will find much comfort in the knowledge that, as quickly as one panacea dies out or becomes disgraced, the ingenuity of the chemist produces another, and exclaims, in the words of Hood's pedler, "The last new patent, nothing comes nigh it."

Resolutions of Thanks for Drs. G. A. Peters and Newton M. Shaffer.—At a meeting of the Board of Managers of St. Luke's Hospital, New York, held January 30, 1888, the following resolutions were adopted:

Whereas, On the 23d of December, 1887, this Board received the resignation of Dr. George A. Peters as Attending Surgeon, and at the same meeting appointed him Consulting Surgeon; and

Whereas, Dr. Peters was a member of the Medical Staff of this Hospital at its first organization, March 1, 1859, and has already served our patients for over twenty years as Attending Surgeon, and for over eight years as Consulting Surgeon; therefore,

Resolved, That in accepting the resignation of Dr. George A. Peters, this Board desire to place on record their grateful appreciation of his long and faithful service, which has left a deep impress on the professional work of this Hospital and has contributed largely to the reputation this Hospital has won for skilful and conservative surgery. The vast increase in the surgical work of this institution, as this Board believe, in no small degree is due, not only to the fact that our Hospital Staff have kept abreast of all well-ascertained improvements in method, but because a zeal for surgical achievement has always been held back from rash and venturesome experimenting by the restraint imposed by a Christian belief in the sacredness of the human body as the temple of an immortal spirit, and by a high sense of responsibility toward those helpless sufferers who submit themselves trustingly to our physicians' and surgeons' skill.

Resolved, That this Board hereby order that these resolutions be entered in full on the minutes of this meeting; that a copy of them shall be suitably engrossed and sent to Dr. Peters, and that they be published in The Medical Record.

Whereas, On the 23d of December, 1887, this Board received the resignation of Dr. Newton M. Shaffer as Orthopedic Surgeon of this Hospital, and at the same meeting appointed him to a new office, then created, that of Consulting Orthopedic Surgeon; and

Whereas, Dr. Shaffer has served this Hospital continuously for over fifteen years, having been provisionally appointed as Orthopedic Surgeon in May, 1872, and his appointment being confirmed with the unanimous approval of the Medical Staff and of the Board of Managers, May 26, 1873; and

Whereas, The method of treatment used in the New York Orthopedic Dispensary and in St. Luke's Hospital by Dr. Shaffer has now become nearly universally recognized among scientific men as the most successful mode of treatment of spinal and joint diseases, and now results in diminishing very largely the mortality from a class of diseases which were formerly regarded as practically incurable; therefore,

Resolved, That in accepting the resignation of Dr. Shaffer as Orthopedic Surgeon, with the duties of a continuous service; in his appointment as Consulting Orthopedic Surgeon, to make weekly advisory visits; and in the appointment as his successor, as Attending Orthopedic Surgeon, of Dr. John Ridlon, who has been trained for the position under his tutorship, this Board desire to express their high appreciation of the valuable services Dr. Shaffer has rendered in the wards of this institution to suffering humanity, and of the achievements his skill, fidelity, and patience have won for orthopedic surgery.

Resolved, That this Board hereby order that these resolutions be entered in full on the minutes of this meeting; that a copy of them shall be suitably engrossed and sent to Dr. Shaffer, and that they be published in The Medical Record.

(Attest,) Geo. Macculloch Miller,
Secretary.

New York Ophthalmological Society.—At the Annual Meeting of the New York Ophthalmological Society, the following officers were elected for the year: *President,* J. D. Rushmore, M.D.; *Vice-President,* W. Oliver Moore, M.D.; *Secretary,* W. S. Dennett, M.D.

"The Physiology of a Rogue" is the curious title of a paper to be read by a legal gentleman at the next meeting of the Society of State Medicine and Medical Jurisprudence, to be held at the Academy of Medicine, February 9th.

Orange Mountain, N. J., Medical Society.—The following were elected officers of the Orange Mountain Medical Society, at the Annual Meeting on January 27th: *President,* Dr. George Bayles, Orange; *Vice-President,* Dr. W. H. White, Bloomfield; *Secretary,* Dr. T. W. Harvey, Orange; *Treasurer,* Dr. T. R. Chambers, East Orange.

Dr. George A. Crosby, one of the most prominent physicians in New Hampshire, died at Manchester, on January 29th, of congestion of the brain, after a two weeks' illness. Dr. Crosby was born in Lowell, Mass., in 1831, and came from a race of distinguished physicians. He was graduated at Dartmouth in 1852. Dr. Crosby had been President of the New Hampshire Medical Society, and was a member of the Manchester Board of Health at the time of his death.

Dr. James E. King, one of the oldest physicians in Buffalo, N. Y., died recently, aged sixty-five.

A Doctor's Epitaph.—Dr. Benjamin Eddy Colting, after a professional experience of over half a century, says, in a recent address (*Boston Medical and Surgical Journal*): "If, perchance, a professional epitaph be ever sought for—to indicate a life-aim, and to conform more nearly to truth than most such tributes to the dead—let it be: '*He cured the sick without drugs.*'" Dr. Gray, the homœopath, *per contra,* once said that the epitaph on his tombstone should be "Antimony."

The Medical Society of the State of New York will commence its sessions on Tuesday of next week, at Albany. Delegates from this city are reminded that reduced rates of fare can be obtained by application to Dr. Clarence C. Rice, Secretary of the New York delegation.

A dispute has lately arisen in Paris between M. Zola and M. Sarcey over the question whether asses can vomit. Asses cannot, under ordinary circumstances, vomit. But they are not given a fair chance. Let the poor animals have read to them some of M. Zola's washtub realism, or, say one of his chapters on obstetrics, small-pox, or delirium tremens. Then observe the emesis.

Reports of Societies.

THE PRACTITIONERS' SOCIETY.

Stated Meeting, January 6, 1888.

DR. GEORGE L. PEABODY, PRESIDENT *pro tem.*

DR. BEVERLEY ROBINSON reported

TWO CASES OF HYPERTROPHY OF ADENOID TISSUE IN THE EPIGLOTTIDEAN FOSSA (TONSIL OF THE TONGUE).

In Case I. enlarged tracheal glands (?) gave signs due to pressure of the first portion of the respiratory tract. These signs were at first thought to be suspicious as regards tubercular deposit at the apex of the right lung. Careful examination of the sputa under the microscope, after staining, not revealing any bacilli, and the patient's general health having notably improved, led to the belief that phthisis was not present. During the treatment of the case, by means of chromic acid applied locally with a McCoy's applicator, excessive dyspnœa occurred. The patient's death appearing imminent, Dr. Robinson introduced one of O'Dwyer's tubes, which was rejected after a few moments, during a severe paroxysm of cough. Owing to paralysis of the right vocal cord, ineffectual attempts were made by Dr. Robinson to introduce a larger O'Dwyer's tube, on each occasion the tube being arrested apparently by impact with the fixed cord. These manœuvres, though ineffectual, afforded some relief to the patient's breathing. Within a short time she began to spit up pus abundantly, which was continued during forty-eight hours, and was accompanied and followed by great improvement of respiration. It was presumable that the passage of O'Dwyer's tube had caused an abscess of the peritracheal glands to open into the trachea, and by the relief thus obtained took away much of the dangerous pressure on the trachea. The patient was examined by several members of the Society, who recognized the enlarged mass at the base of tongue, and the paralyzed right vocal cord. Despite these conditions, however, the patient now breathes quietly, and is only conscious of difficulty of respiration when she exerts herself. The prolonged harsh inspiration and expiration can still be heard at the apex of the right lung, but with less intensity than formerly. The sounds of the voice are perhaps slightly hoarse, but certainly not to such a degree that one could diagnose the laryngeal paralysis without the aid of the laryngeal mirror.

CASE II.—A young lady, single, a teacher, came to my office this morning, and at my request wrote me out the following brief history, which I shall read to you precisely in her words:

"Until within the past four years my throat was perfectly strong, and, save occasional hoarseness, due to cold, I never had any trouble with it. I read aloud and sang without discomfort or fatigue for two or more hours at a time.

"The summer of 1884 I first began to feel a slight effort in singing; this increased, and the sound died away, or rather slipped back, in my throat. I was not very strong at the time, and attributed my weakness of voice to that fact. In the early autumn of the same year I took a severe cold, and coughed for several weeks; my throat was painful. I was very hoarse, and at times could not speak above a breath.

"When my cold left me, and I tried to talk much, and read aloud, I found my throat very weak, and often a dull ache would come. My singing voice was utterly gone, I could not make a sound. I took tonics, gargles, etc., and after some time I found I could sound the middle notes, but even this was an effort and I tried no more.

"Since then, more than three years ago, my voice has continued weak. I am unable to talk or read aloud for any length of time without fatigue. If very tired or nervously excited, my voice dies away; and on two occasions, December 10, 1887, being the last, my voice has entirely left me.

"I am twenty-six years of age.

"C. G. H."

In the case I have just reported, the hypertrophy of the adenoid tissue at the base of the tongue was very similar in amount and general appearance to that of the first case. There was, however, no accompanying condition of limited laryngeal paralysis, and it is evident, therefore, that if the peritracheal glands be enlarged, they at least do not compress to a notable degree either the recurrent nerve or the trunk of the vagus itself.

Cases similar to those I have described are infrequently met with. In fact, in my own experience, they are the only cases that I have ever recognized. Possibly I have seen such cases previously, but if so, they have passed unremarked. In my reading, my attention was first directed to the existence of this hypertrophic condition at the base of the tongue by an article in THE MEDICAL RECORD, November 8, 1884, by Dr. H. Holbrook Curtis. Dr. Curtis regards the condition as being occasioned by a wrong vocal method, and as not uncommon among professional singers in whom the voice is improperly used in speaking, and especially in singing. Before Dr. Curtis, I find, on reference to my authorities, others had remarked this peculiar hypertrophy of the lingual tonsil, and had described different symptoms connected with it. Since Dr. Curtis' article, Stoerk, Rice, McBride, Gleitsmann, etc., have written interesting communications in regard to this subject. At the end of Dr. Gleitsmann's article in THE MEDICAL RECORD of December 17, 1887, the literature of the matter, up to date, except Dr. McBride's article,[1] may be found.

So far as I know, no case at all similar to my first case has hitherto been recorded. As a matter of additional interest, I would say that my first case was examined by Mr. Lennox Browne, of London, and Dr. George M. Lefferts, of New York, who agreed substantially with me in my opinion of it. My second case was seen by Dr. H. H. Curtis.

DR. A. A. SMITH read a paper entitled

CLINICAL OBSERVATIONS ON DILATATION OF THE STOMACH [see p. 120].

DR. ROBINSON, referring to the matter of diet in this disorder, said that in his experience he found that food or drink which seemed least likely to be beneficial on physiological grounds sometimes proved to be the best. He cited the case of a patient who lived for a long time on *pâté de foie gras*; and another case in which brown stout and lager beer relieved nausea and vomiting after the usual remedial measures failed.

DR. ANDREW H. SMITH said that it was sometimes very hard to diagnosticate an enlargement of the stomach. In his experience auscultatory percussion furnished the most help.

A plan had been suggested of passing a tube into the stomach, with a rubber balloon at the end, which was then inflated. This had not practically worked very well. In treatment, washing out the stomach had done more than anything else; but in bad cases the chances of recovering the tone of the stomach were very small. Non-fermentative food should, of course, be given.

He had thought of employing

RECTAL ALIMENTATION

for a long period of time.

DR. DANA referred to the fact that the stomach may suffer from attacks of acute dilatation, just as the heart and other hollow viscera do.

He cited the case of an anæmic woman suffering from spinal irritation, who had "crises" of intense neuralgic pains, accompanied with enormous dilatation of the stomach, the attacks lasting for several days. In these cases there was, apparently, a vaso-motor paresis of other abdominal viscera, as shown by the copious discharges of pale urine.

---

[1] Edinburgh Medical Journal, September, 1887.

Dr. Kinnicutt said that the acute dilatation referred to by Dr. Dana had been described by several writers on diseases of the stomach. His experience did not coincide with Dr. Smith's as to the comparatively rare existence of dilatation of the stomach. He believed that, in varying degrees, it was of frequent occurrence. A diagnosis of gastrectasia, when present, was certainly very desirable, but without a diagnosis of its probable cause we should oftener fail than succeed in attempts to relieve it. Dilatation of the stomach, aside from its production by pyloric obstruction, had its origin in retardation of digestion, through which more or less food was constantly present in the stomach. The causes of such retardation were to be found (*a*) in excessive gastric secretion; (*b*) in diminished secretion; (*c*) in abnormal fermentation; (*d*) in impaired muscular powers of the stomach-walls. Lavage was indicated in gastrectasia due to any of these causes; but it must be supplemented by other treatment. Riegel's investigations, of the past several years, afforded, it seemed to him, the only scientific basis for such supplementary therapeutics. Riegel's therapeutics were based almost wholly upon chemical examination of the secretion of the stomach. His method consisted in giving a "test meal" of mixed food, and in withdrawing the contents of the stomach, undilated, six hours later, by means of a stomach-tube. The stomach should be empty at the expiration of this time, and therefore the withdrawal of portions of undigested food after this interval would indicate a retardation of digestion. The filtrate is then submitted to a chemical examination, and its digestive power is also artificially tested. Riegel had found, in various diseases of the stomach, the following conditions:

1. An apparently normal secretion.
2. A diminution in, or an absence of, free hydrochloric acid, with an abundance of organic acids and an absence of peptic strength.
3. The presence of hydrochloric acid, with a large amount of organic acids.
4. An excessive amount of hydrochloric acid. The appropriate treatment of these varying conditions of the gastric secretion must be instituted, as they severally existed.

Dr. Kinnicutt's comparatively limited experience wholly coincided with Riegel's, Ewald's, and Gerhardt's, as to the absence of free hydrochloric acid in cases of cancer of the stomach. Its constant *presence* in large amount, he believed, *positively* contraindicated the presence of cancer. He thought that the color-tests, when carefully used, might be considered as reliable in determining the presence or absence of free hydrochloric acid.

Dr. Peabody said that one method of assisting in diagnosis was to determine the time which substances remain when taken into the stomach. In dilatation food naturally did not pass out of the stomach so rapidly as in normal states. This point could be easily determined by causing the patient to swallow a medicinal dose of salol. This drug is not soluble in any but an alkaline medium. As soon as it reaches the duodenum it splits up, becomes dissolved and absorbed, and salicylic acid soon appears in the urine, in which it can be recognized in the usual way. Ordinarily the reaction can be obtained within fifteen minutes after swallowing the salol. If it is delayed an hour it shows that the stomach does not discharge its contents so rapidly as usual.

Dr. A. A. Smith had tried this test in one case with satisfactory results. But as to the length of time in which a substance may stay in the stomach of the healthy, he thought there were great variations. He knew of a case in which a patient took quinine pills daily for six successive days. On the sixth day she vomited twenty-three of them. She had had no evidence of gastric disturbance. Riegel cited a case in which a patient vomited cherry-stones twelve months after they were swallowed.

Dr. Smith agreed with Dr. Robinson as to the uncertainty in attempting to formulate diets.

As to auscultatory percussion in the diagnosis of dilated stomach and abdominal growths, he had been disappointed with it. It was a much more satisfactory method in thoracic than in abdominal disorders. He had used rectal alimentation entirely in a case, for five weeks, with success. He referred to cases in which he made patients swallow large quantities of water (two to three pints) for purposes of diagnosis.

Dr. Kinnicutt thought it would be rather difficult sometimes to make patients drink that amount of water. He had filled the stomach by means of a siphon tube. Patients rarely objected to its use after a first trial.

Dr. J. West Roosevelt thought that in spite of the high authority for the use of the tests for the presence of hydrochloric acid in the stomach, it was a very difficult thing to do, especially when inorganic acids are present in the stomach. The tests by color are very unreliable, especially for quantitative work.

Dr. Kinnicutt said that it was not claimed that the test was quantitative. He thought they furnished valuable evidence as to whether the hydrochloric or organic acids were present or absent. They were based on high chemical authority, and have been employed thousands of times.

Dr. A. H. Smith asked at what time in the period of cancerous diseases this change takes place.

Dr. Kinnicutt said that in the beginning the acids were simply diminished, but later on the free hydrochloric acid entirely disappeared. In four or five cases in which he had applied this test the acid was absent.

Dr. Ball suggested that the fact of this acid being present in early stages of cancer, when diagnosis was most difficult, was rather against its usefulness.

Dr. Kinnicutt said that the acid was sometimes absent in cases of gastric catarrh, also when bile is in the stomach, and in certain cases of anæmia, but the strong point was that its *presence* excludes the existence of cancer.

Darwin as a Medical Student.—The late Mr. Charles Darwin belonged to a race of physicians, and in 1825 he was sent to Edinburgh to study medicine. The two sessions spent there were to him "intolerably dull," because the instruction was by didactic lectures. Dr. William Osler, writing of this subject in the *Canada Medical and Surgical Journal*, says that Darwin speaks of Dr. Munroe's lectures on human anatomy as exciting disgust, and adds "it has proved one of the greatest evils of my life that I was not taught dissecting, for I should soon have got over my disgust; and the practice would have been invaluable for all my future work." Evidently his lack of interest was due in great part to absence of practical instruction, for during the summer, in his father's office, he took the greatest pleasure in the study of cases, and at one time had at least a dozen patients. He seems to have had an instinctive horror at the sight of blood, a trait derived from his father, who, curiously enough for a practitioner in those days, "could scarcely endure to see a person bled."

Scheele's Test for Abdominal Aneurism.—To the signs and tests given by Dr. Philips we add that suggested by Scheele in the *Berliner Klin. Wochenschrift* of July and August, 1878. This consists in making firm simultaneous compression of both femoral arteries for a few seconds. If there be aneurism patients will immediately complain of pain in and around the tumor. Otherwise it will give only ordinary discomfort.

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, January 11, 1888.

T. Mitchell Prudden, M.D., President, in the Chair.

The President referred to the great and irreparable loss which the Society had met with in the death of its Secretary, Dr. Wesley M. Carpenter. Dr. Carpenter had been ill for some time, but with his characteristic fortitude he had kept his ailments largely to himself. Probably the last work that he had done had been for this Society. He attended a meeting of the Board of Trustees, at the house of Dr. John C. Peters, on the evening before his death, and although apparently not feeling at all well on his return home, he had carefully written out the minutes of the Board meeting before retiring. This was not the time to express the Society's appreciation of Dr. Carpenter's work or its admiration of his character. The duties and tasks which his hands had dropped must now be taken up and carried forward as best they could.

Dr. G. C. Freeborn was then elected Secretary *pro tempore.*

Dr. J. S. Thacher, from the Committee on Microscopy, reported that the abdominal tumor presented by Dr. Lewis H. Sayre, on behalf of a candidate, December 9, 1887, showed a structure consisting of fibrous connective tissue, which was, in a few small spots, rich in small round cells. It should therefore probably be classed as a fibroma.

Dr. Ira Van Gieson presented a specimen of

MULTIPLE TUMORS FROM A DOG.

There was a brownish-white, dense nodule, about half an inch in diameter, just above the left external canthus, composed of loose fibrillar connective tissue, with numerous pigmented connective-tissue cells. Some of the mesenteric glands were enlarged, and contained soft white nodules consisting of closed, thin-walled blood-vessels surrounded by clusters of cuboidal and polygonal cells, which in places were swollen and filled with vacuoles. The anatomical diagnosis was: Pigmented fibroma of the brow; angio-sarcoma of the mesenteric glands.

Dr. Hodenpyl presented a specimen of

VERRUCOUS ENDOCARDITIS WITH ASSOCIATED LESIONS,

removed from the body of a woman forty years of age. The patient had extensive general anasarca. The pericardial sac contained four ounces of clear serum. The heart weighed five hundred grammes. There was dilatation with hypertrophy of the left ventricle. The aortic valve was much thickened and in places eroded, and some vegetations were seen on the free surface of the valve. The mitral valve was thickened and stenosed, and very rigid. There was a slight degree of calcareous degeneration in the aorta.

The left lung was enlarged and consolidated in its upper two-thirds, and on section presented a brownish-red color. The liver, which was not shown, was cirrhotic. The kidneys were enlarged and hard. The spleen was enlarged and hardened, and in one portion showed a white infarction. No bacterial examination of the heart-vegetations had been made.

The President said that not many cases of this kind had been shown to the Society of late, the specimens having been mostly of the ulcerative variety.

The President referred to a report of fourteen cases of endocarditis, seen in Vienna, in which an

EXAMINATION FOR BACTERIA

had been made. Micro-organisms had been found in twelve of these cases. These were all instances of ulcerative endocarditis, but the two cases in which no bacteria were found were examples of simple vegetative endocarditis. It would seem, from the results of medical research at the present time, that bacteria are not apt to be present in cases of simple verrucous endocarditis. The bacteria most commonly found were the streptococcus pyogenes and the staphylococcus pyogenes aureus. In some cases, in which pneumonia was present, Weichselbaum had found the pneumococcus. One or two other varieties of bacteria had also been found. He further suggested the advisability of injecting the valves in these cases. The heart-valves were not vascular, except at their bases. In vegetative endocarditis, however, the valves had been found to be vascular, but the vessels were very minute and their presence could be demonstrated only by careful injection.

Dr. Northrup recalled the fact that the President had examined a case of ulcerative endocarditis in a child last summer, and had found bacteria present.

The President said that the micro-organisms found in this case were slender bacilli. The specimen had been kept in Müller's fluid for some time during the warm weather, and he feared that possibly this fact might account for the presence of the bacilli, which may have worked their way into the large thrombus on the valves. There had, however, been two or three apparently similar cases reported in which this possible source of error had not been present.

Dr. E. C. Wendt had never heard of a case in which bacilli had been found in this form of endocarditis. He thought it was well always to bear in mind the necessity for quick work in these examinations, as mistakes might readily occur through the intrusion of bacteria from the air.

Dr J. West Roosevelt presented a specimen of

PYO-PNEUMOTHORAX DEPENDENT UPON PHTHISIS.

The specimen was removed from the body of a young man who died in Bellevue Hospital. He had suffered from the ordinary symptoms of phthisis for eight months before his death. He gave no history of sudden pain in the chest, or of shock such as usually follows perforation of the lung. The points of interest were the rather peculiar physical signs and the curious lesion. Two days before his death the patient had tympanitic resonance over the lower part of the right chest, with amphoric breathing and voice, metallic tinkle, and a marked succussion sound. To the bottom of the chest, behind, bubbling and subcrepitant râles were plainly audible. The autopsy showed, in the left lung, numerous discrete yellow nodules, the size of a pea.

Between the base of the left lung, the diaphragm, and the costal pleura was a cavity lined with a shreddy, whitish pellicle, and containing about one and a half pint of bad-smelling pus. The abscess-cavity extended upward behind the lung as a narrow channel, alongside the vertebræ, to within three inches of the apex of the lung. This channel passed between the layers of adherent pleura. At the upper part there was a space about two inches square, which was composed of pulmonary tissue, which was not covered with the pellicle. The lung-tissue was eroded and had a pitted appearance, and at this point there was communication with one of the bronchi. The eroded pulmonary tissue looked very like an old tubercular cavity.

The speaker called attention to the fact that, although the cavity contained considerable pus, it gave tympanitic resonance to the very bottom, and also beneath the fluid-level subcrepitant râles were audible. He had heard the

SUBCREPITANT RÂLES BENEATH THE FLUID-LEVEL

in several cases of pleurisy with effusion, and in one case, where the chest was full to the top, these râles were audible to the very bottom. How such sounds were produced was not clear to him. The tympanitic resonance heard seemed to have been caused by the cavity, and it was probable that, even when percussion was made over the fluid, the tympanitic sound from the air above it masked the dulness.

Another point of interest was the question whether the pyo-pneumothorax had been produced by the rupture of a cavity within the lung, or whether an empyema had first occurred, and had then burrowed up behind the lung and perforated it. This point he was unable to decide.

DR. NORTHRUP asked what explanation the speaker had to offer for absence of dulness at the base of the lung.

DR. ROOSEVELT replied that he saw no other explanation than that the fluid in the pleural cavity and the solidified lung offered a good conducting medium through which the resonance from some dilated bronchi was transmitted. A somewhat similar effect was noticed when a portion of the intestine was known to be filled with fluid, yet a tympanic resonance was transmitted through it.

DR. J. C. PETERS called attention to Skoda's work, in which an attempt was made to explain these acoustic puzzles.

The Society then went into executive session.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE ANTI-VACCINATION MOVEMENT—A NEW SUGGESTION—MR. REGINALD HARRISON ON URINE FEVER AND ITS CAUSE—PROPHYLACTICS—A MEDICAL CLUB—REPORT OF THE COMMITTEE ON THE DISPOSAL OF THE WOMEN'S JUBILEE OFFERING—THE REFLEX INHIBITORY ACTION OF CUCAINE—CUCAINE IN URETHRAL SURGERY—TEMPORARY LIGATURE OF CAROTID ARTERY—SUCCESSFUL REMOVAL OF FOREIGN BODY FROM LEFT BRONCHUS—THE DISCUSSION ON HOMŒOPATHY—A MEDICO-LEGAL CASE.

LONDON, January 9, 1888.

WITH all our efforts, the anti-vaccination movement in England is far from dead, but, on the contrary, rather on the increase. There are, it is true, Acts of Parliament rendering compulsory the vaccination of every child within three months of its birth. Penalties are imposed for non-compliance with the law and steps taken to make it known by making it a part of the duty of every registrar of births to hand to every person registering a birth a paper containing full instructions and the name and address of the nearest public vaccinator, who will perform the operation free of charge. All this sounds very satisfactory; but what is to be done in such towns as Leicester, where the bulk of the population, and nearly all the municipal officers, are opposed to vaccination? If fines be imposed, they cannot be recovered, and it is impossible to imprison the majority of the inhabitants, especially when the authorities with whom rests the duty of carrying out the law are active sympathizers with those who break it. In such districts, therefore, the law as to vaccination practically remains a dead letter, and is likely so to remain until a terrible epidemic of variola awakens the inhabitants. In this dilemma, various expedients have been proposed. I referred some time since to a suggestion made by Sir Joseph Hooker, that vaccination might be shorn of much of its terrors to fond mothers by reverting to Dr. Rigby's plan of making only one puncture instead of several. This, however, was promptly decried in the medical press. Another proposition, recently made by Dr. Bond, Medical Officer of Health for the Gloucestershire Combined Sanitary District, does not seem likely to meet with any more favorable reception from the profession. Dr. Bond proposes to extend the age within which vaccination must be performed from three months to two years, and he believes that few parents would object to the performance of the operation on children who had attained to nearly two years of age. The obvious objection to the plan is that the younger children would be left unprotected, and this point has been promptly pointed out by another medical officer of health writing to *The Times* on the subject in response to Dr. Bond's letter, which appeared in that journal. Another difficulty, and one recognized by Dr. Bond himself, is that children would pass out of sight and remain unvaccinated, a difficulty which he endeavors to minimize by the remark that they will come under observation again when they go to school. *The Lancet* seizes on this point and remarks that if attendance at school is to insure vaccination of the children it will add yet another to the objections entertained by many parents to the education of their children. I am afraid we must resume our old ground and trust to moral suasion and the spread of education. Our temperance friends have gained far more victories by these agents than by their hitherto unsuccessful endeavors to alter the liquor laws.

In his first Lettsomian Lecture, delivered before the Medical Society of London, Mr. Reginald Harrison, of Liverpool, dealt at some length with what he prefers to term "urine fever." He discards the phrase "urethral fever," as it seems to connect the symptoms produced rather with the precise part than with the process. Mr. Harrison said he believed that wherever throughout the urinary tract urine could be placed under certain conditions all the phenomena usually associated with the term "urethral fever" could be produced. He especially insisted on the action of urine in recent wounds, a matter which he tested a short time since in a series of cases in which he performed internal urethrotomy. In all of them, after performing the operation for the relief of stricture, he also performed median cystotomy and passed in a full-sized tube so as to drain the bladder without allowing any urine to flow over the wound. *Urine fever only occurred where this drainage was imperfect.* In cases where it followed catheterism, the lecturer said he thought it was due to urinary absorption at places where the epithelial lining of the urethra had been rubbed off. Where futile attempts at catheterism had been followed by supra-pubic aspiration and the urine thus drawn off without coming in contact with the injured part of the urethra, he had never known rigors or fever follow, even where the amount of injury to the urethra had been considerable. It seemed probable, he remarked, that the development of urine fever was really due to the absorption of some poisonous compound derived either from urine, or tissue, or wound-decomposition, or from all combined. An important practical point was pointed out, viz., that these toxic changes in connection with the urine might be prevented. Certain antiseptic precautions considerably reduced both the frequency and the severity of the attacks. This was chiefly noticeable in connection with the use of solutions of corrosive sublimate for irrigating the wound, as well as for retaining within the bladder. Also, certain drugs, by their elimination in some degree through the urine, seemed to render the latter less capable of exciting a specific fever where it remained in contact with a recent wound. This was most marked in the case of quinine. Boracic acid was also a prophylactic.

A medical club in London is not very promising. Some years ago we had one which held forward its characters pretty prominently by taking the name of "The Medical Club." It, however, finally expired after dragging out a precarious existence for some years. I have for some months been cognizant that an attempt was being made to start another, but the formal announcement of the "Galen Club" has only been made within the past week. I am not very sanguine as to its success. Many doctors are not club men at all—they have not the leisure. Those who frequent clubs at all would scarcely care to go to one where they would merely meet "brother chips." The Galen Club, however, is to have a social as well as a medical element, for it is to be conducted on such liberal lines as to admit, not only medical students, but actually laymen who entertain friendly feelings toward the profession. I have also heard it stated that a room is to be set apart for members with "Bohemian proclivities," whatever that phrase may be taken to imply.

The report of the committee appointed by the Queen to consider the best means of so applying the Women's Jubilee Offering as to carry out Her Majesty's wishes on the subject, viz., to apply it for the benefit of nurses and nursing institutions, has just appeared. It is signed by the Duke of Westminster, Sir Rutherford Alcock, and Sir James Paget. The report suggests that an institution be founded for promoting the education and maintenance of nurses for the sick poor in their own homes; that it have its chief centre in London, but that similar central institutions should be located in Edinburgh and Dublin, and that with these institutions should be affiliated others carrying out the objects of the foundation. They further suggest that the official work of the institution should be done in connection with St. Katherine's Hospital, an institution dating from 1148, and having assigned to it in 1351 (by the charter granted by Queen Philippa) the visitation of the sick and poor among its chief purposes.

Two papers of unusual interest were read at the last meeting of the Medical Society of London. The first was by Mr. Harry Fenwick, and dealt with the reflex inhibitory action of cucaine as observed by him in an extensive series of cases. He had found that pain in various parts of the body was temporarily relieved by the injection into the urethra of a twenty per cent. solution of cucaine. This reflex inhibitory action was demonstrated on some decapitated frogs. The leg of such a frog, when placed in a weak acid solution, was rapidly jerked out in some fraction of a second; but, if cucaine had been previously injected into the bladder or rectum, the leg was not withdrawn until after twenty or thirty seconds. This inhibitory power was only observed when weak acid solutions were used. Cucaine possessed no power of delaying the reflex excitability consequent upon stronger acid solutions. From his observations Mr. Fenwick concluded that slight nerve-irritations of any part (as neuralgias) could be relieved by injection into the urethra of a few drops of a ten or twenty per cent. solution of cucaine. Severe nerve-irritations, however, as in the pain of cancer, inflammation, etc., could not be thus relieved. Mr. Fenwick had also found these observations of use in making a diagnosis. Thus, if the urethral injection of cucaine immediately relieved a renal pain, he concluded the latter to be due to some slight irritation, as from gravel, etc. If the renal pain were unrelieved, he diagnosed more serious disorder. Illustrative cases were mentioned. Mr. Fenwick then drew attention to the value of cucaine in preventing (by its inhibitory action on the renal circulation) damage to an unhealthy kidney during operations upon the bladder and urethra. M. Tuffier's experiments upon renal congestion produced by distending the bladder or injuring its walls were mentioned, and it was suggested that this flooding of the kidney, with its consequences, might be wholly or partially prevented by the use of cucaine.

Mr. Treves then read a paper on a method of controlling hemorrhage from branches of the carotid arteries. It was usual to ligature the carotid trunk, but much might be done by applying temporary pressure to the main trunk. As this could not be done with success in the neck, he proposed to isolate the common carotid, pass a catgut loop round it, and constrict the latter so as to check the passage of blood. He had employed this method in several cases, and only one proved fatal; in all, the lumen of the artery was ultimately restored.

At the Medical and Chirurgical Society, on Tuesday last, a paper was read (of which Dr. Cheadle and Mr. Thomas Smith were joint authors) giving the history of a case in which a metal pencil-cap passed down the left bronchus. Eleven days after the accident there was marked dulness over the whole of the left side of the chest, an almost total absence of respiratory murmur on the same side (air entering only over a limited portion of the upper part in front), and great retraction of the left side of the chest. There was then no dyspnœa, as at first, but frequent short cough. The isthmus of the thyroid having been divided, tracheotomy was performed, the edges of the tracheal wound attached to the edges of the skin-wound so as to keep the trachea widely open, and the pencil-cap readily extracted by means of forceps. With the exception of a short pyrexial attack, the patient made a rapid and uninterrupted recovery. The lung slowly expanded, and fourteen days after the operation the only abnormal physical signs were slight deficiency of respiratory murmur and of expansion on the left side. By a reference to statistics it was shown that the entrance of a foreign body into the left bronchus is by no means so infrequent (compared with the right) as is commonly believed.

The recent dispute at the Queen's Jubilee Hospital has brought forward somewhat prominently before the public the question of homœopathy and its merits. Pending the appeal to the law courts, some of the parties concerned have rushed into print in the lay press, and for some days past the columns of the *Times* have teemed with lengthy letters on the subject. Most of the writers seem to have entirely lost sight of the question at issue, and have chiefly concerned themselves with defending or denouncing homœopathic principles. The latter seem to have changed somewhat since they were last taken out to be aired in public, for (oh, shade of Hahnemann!) we are informed that acceptance of the principle of infinitesimal doses is not now an integral part of the creed. The recent controversy, also, seems to have gained another friend—if not an adherent—to the homœopathic cause, for Mr. Millican, while professing himself an allopath, goes out of his way and takes considerable pains to show that, although he is not convinced of their truth, there is nothing absurd or impossible in the principle of *similia similibus curantur*, or even in that of infinitesimals. The homœopaths have appealed with considerable glee to the considerable number of homœopathic remedies to be found enumerated in the therapeutic works of Drs. Ringer and Brunton. No one supposes that either of the latter gentlemen is a homœopath, but it must be confessed that neither of them has come forward and given any satisfactory answer to the charge of having "annexed" homœopathic drugs and methods of treatment. Both of them have wisely refrained from joining in the mill in the present case. The chief attacks on the principles of homœopathy have been made by two gentlemen sheltering themselves behind the initials of "R. B. C." and "I. C. B.," respectively. The former says he appends only his initials because he does not wish for an advertisement, but as, at the same time, he remarks that those of his own profession will sufficiently recognize him by those initials, it is evident this is rather a vainglorious pretence. So far as his professional brethren are concerned, the advertisement is as great as if he signed his name, for but few will fail to recognize "R. B. C." as Mr. R. Brudenell Carter, who, by signing only his initials, escapes (with the public) the odium of persecuting the homœopaths. It is equally transparent that "I. C. B." is Dr. J. C. Bucknill. I am afraid both these gentlemen, although delivering some telling blows on their adversaries, have somewhat damaged their own cause by their warmth, and would recommend them to be satisfied, for the future, with cultivating their own special fields of ophthalmology and alienism, respectively. Lord Grimthorpe is by far the most vigorous of those who defend the homœopathic camp, although he is but a layman, and by no means so judicial and impartial in his advocacy as his forensic training would lead one to expect. Although he takes a hopelessly wrong view, it is most enjoyable to read his letters. He asserts that the "allopaths" have no scientific principles, as his party has, and quotes from various medical writers to support this conclusion. Your readers can imagine his deductions. In his last letter he winds up by praising bone-setters and referring to the incredulity displayed toward Harvey by his contemporaries.

A case of some interest to the profession was finally decided in the law courts a couple of days since. A lady who had been attended in her confinement by two medical men had had an operation performed upon her. Suppuration followed, and it was contended that the special precautions necessary in the after-treatment of the case had not been observed. The patient and her husband brought an action for malpraxis against the doctors. The latter defended the action, and obtained a verdict in their favor, the jury, however, adding, as a rider to their verdict, "that there was not sufficient medical supervision of the nurse." The counsel for the plaintiffs said this came to a verdict for them, but the judge thought otherwise, and entered the verdict for the defendants. Against this judgment the plaintiff and her husband now appealed, on the ground that the finding of the jury as to the want of proper directions to the nurse really amounted to a verdict of negligence against the medical men. The Court, however, said there was no ground for the present application, and dismissed it. Mr. Baron Huddleston said it was plain that the case now set up was not that originally set up, nor that for which the action was brought. The action was brought for alleged want of care in the defendants as to the confinement, and when the plaintiffs' case failed as to that they set up the uncleanliness of the nurse, which was her fault, not the doctors'. Mr. Justice Manisty concurred.

INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In your issue of January 21st Dr. Loring returns to his assault, reiterating his charges that there are no important problems yet to be explained respecting the insufficiencies of the ocular muscles; that the subject is well understood by the "ordinary student of ophthalmology," and that there is nothing new in what I have written in respect to it. I have shown in my reply to his former communication that the text-books in common use, and which fairly represent the status of the question, give but meagre space to this important branch of ophthalmology, and that they do, as I had stated, "practically ignore or barely mention" other insufficiencies than that of the internis. So notorious is this fact to everyone familiar with the subject of ophthalmology that the statement appeared trite, yet my critic now returns to the charge, arraying against the statement "the long and exhaustive articles" of Von Graefe, Alfred Graefe, Giraud Teulon, Woinow, Knapp, and others. We are now able to judge of the sources of authority for my critic's assumption that this subject has been fully dealt with, and I am prepared to assert that one who supposes that the writers cited above have treated this subject in an adequate manner is either ignorant of the works of these distinguished authorities, or blind to the merits of the subject itself. The writings of everyone of the authors cited fully sustain the statement that the literature of insufficiencies is inadequate, and, unless other authorities are found, it is clearly shown that prior to my own writings other insufficiencies than those of the interni had been either ignored or barely mentioned.

One could hardly select a better example of the absence of exact knowledge on this subject than the very case to which Dr. Loring points with pride as one of "insufficiency of the externi," on which he had operated twenty years before. This, according to his report, was a case in which there was homonymous diplopia of 30° at twenty feet, and diplopia even at eight inches, when the object was moved to either side of the median line.

Von Graefe, whose authority Dr. Loring appears to think good, says (*Archiv f. Oph.*, Bd. III., l., p. 177): "Strabismus signifies the inability to bring the axes of vision to intersect at a point of fixation lying in the common field of view." Dr. Loring's case, according to this authority, was one of marked strabismus, and was treated as thousands of cases of strabismus had been before it; but because the surgeon could not stand at a little distance from his patient and see one of the eyes squint under the nose, he supposed that he was dealing with a case in which "there was no actual strabismus"—a case of "insufficiency." It is this failure to comprehend the difference between strabismus and insufficiencies that leads certain ophthalmologists, who have heard of operations for strabismus sursumvergens, to suppose that there has been, during many years past, indefinite numbers of operations for "insufficiencies" of the superior or inferior recti. It is from men whose views are cloudy that the strongest opposition to innovations is to be expected, and yet these profess to see nothing really new in proposed advances, because they are incapable of comprehending the difference between the new and the old.

Dr. Loring accuses me of a want of originality, and brings evidence of the character of his case to sustain the charge. Whether my work has been original or not is of little consequence, and is certainly a question which will be settled by broader minds than that of one who reviews a scientific paper which he has not read; and it will not be decided by men unqualified to distinguish between a case of well-marked strabismus convergens and one of simple "insufficiency of the externi." But this subject of originality is a suggestive one. Is it so long ago that oculists in this country have forgotten the purchase of copies of a work on ophthalmoscopy which was supposed to contain something new, but in which, after turning over the pages of letter-press in disappointment, they found at the close a collection of colored lithographs which constituted the expensive element of the work, and which had been familiar to most of them during more than twenty years; and against this publication, of which, in the absence of an international law for the protection of authors, the rightful owners had no means of defending themselves? This part of our subject would bear considerable expansion did space permit.

Whether what I have written is new or old, it is pretty certain that no one who reads what I have written with intelligent attention will probe the nasal ducts of his patients month after month in the vain expectancy of curing the excessive lachrymation arising from hyperphoria. He will not treat his asthenopic patients indefinitely by local applications, while he fails to correct extreme grades of astigmatism and "insufficiencies." He will not attempt, in cases of strabismus sursumvergens, to correct the supposed "insufficiency of the interni" by tenotomy of the externi. A bright man who has read what I have written may make mistakes—even dull men sometimes do that—but he will not continue through months practices such as I have mentioned, which only a failure to understand essential principles could explain. Nor will such a one write up his case of strabismus as one of "insufficiency of the externi" in which there was no strabismus, nor will he quote such a case in after years as an example of the class to which it clearly does not belong.

Dr. Loring sees in the increased attention to the insufficiencies of the ocular muscles one of the saddest pages in American ophthalmology. The wail is the old wail which has been heard all down the ages, when the world has run away from some self-appointed custodian of the glory of his "illustrious predecessors," and who has taken alarm at every innovation, regarding it as a token of disrespect to their memory.

Dr. Loring asserts that years ago Von Graefe and others "divided the superior rectus for insufficiency of the inferior rectus." Will Dr. Loring point us to a single instance reported by Von Graefe, or any of those whom he has named, including himself, in which tenotomy of either the superior or inferior rectus was done in a case of non-strabismic insufficiency? Quite a number of well-informed oculists would be glad to see that report.

The doctor also longs to see the report of the Neurological Society upon these matters. Doubtless the Society will, in its own good time, furnish a report, and doubtless it will be interesting reading.

GEORGE T. STEVENS, M.D.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending January 28, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	13	2
Scarlet fever	127	22
Cerebro-spinal meningitis	1	1
Measles	45	11
Diphtheria	151	53
Small-pox	4	0
Yellow fever	0	0
Cholera	0	0

A NORTH CAROLINA paper says that, from 1814 to 1820, it was as common to cut off a negro's leg as to give quinine is now. The custom arose from the fact that one doctor gained a great reputation from the amputation of a negro's leg. Jealous surgeons then took to cutting off negroes' legs for the slightest cause, as a sore heel, rheumatism, sprained ankle, or stumped toe.—*American Lancet.*

POLYMYOSITIS.—The muscular system is subject to fewer diseases than any other in the body, and is comparatively rarely the site of severe inflammation, even after injury. The observation, therefore, of a form of general myositis, probably of an infectious nature, is a point of considerable pathological interest. Inflammation of certain muscles and a peculiar form of hyaloid degeneration has been observed occasionally as a complication of typhoid fever, but acute and wide-spread myositis occurring as an independent disorder has only recently been recognized. Unverricht, who has given a description of the disease, attributes it to a specific infection, and states that the prominent symptoms are intense inflammatory swelling of the muscles, causing excruciating pain, and accompanied by extensive hemorrhagic extravasation, and by œdema, enlargement of the spleen, and fever. The disease first appears in the extensors of the limbs, and the inflammation is most intense there; but other muscles are also involved, death being due to asphyxia, due to the disease spreading to the muscles of the throat and chest, and so producing asphyxia. This "acute progressive polymyositis" has to be distinguished chiefly from trichinosis; the flexors, however, are earliest and most affected in trichinosis, and the local process was more intense and extensive.—*British Medical Journal.*

STRYCHNIA IN INSOMNIA.—Dr. T. Lauder Brunton finds small doses of strychnia very useful in neurasthenic insomnia.

"SICK HEADACHE," dependent on a bad condition of the stomach, will often disappear in half an hour under the influence of two grains of potassium iodide dissolved in water, and taken in divided doses at intervals of from three to five minutes.—*Dr. J. Aulde.*

QUININE, in doses of one-tenth of a grain, may be given to those who are unable, on account of idiosyncrasy, to take larger doses, and it will often be found that these small doses are sufficient.—*Dr. J. Aulde.*

RADICAL CURE OF HERNIA.—A long series of papers on the radical cure of hernia was read at the annual meeting at Dublin, by Dr. Mitchell Banks, Dr. Macewen, Mr. Arthur Barker, and others, which goes to prove that the method of free incision and exposure of the sac has, in the practice of most surgeons, superseded the subcutaneous method. These papers, together with their accompanying tables of cases, show the comparative safety and the general good results, so far as can be determined at present, of the more modern methods of procedure, but there is still much difference of opinion as to the treatment of the sac, and as to whether the canal and external ring should be closed by sutures or not. Dr. Banks, whose opinions on this subject demand every attention, holds, in opposition, we imagine, to many who have co-operated with him in this special work, that with regard to children operative procedures are very seldom required, and that no person should be subjected to operation who can wear a truss with comfort.—*British Medical Journal.*

CAUSE OF ANÆMIA.—Some light has recently been thrown on the causation of anæmia by the observation that certain forms are associated with intestinal parasites. Lichtheim, of Berne, in his address to the German Congress of Physicians, admitted that bothriocephalus latus has some share in the causation of some of the cases classed as pernicious anæmia; it is generally admitted that anchylostoma duodenale produces a severe form of anæmia; and it has recently been suggested by Erni, and also by Kynsey, that a certain proportion at least of the cases of beriberi were due to the presence of the same parasite, or of tricocephalus dispar. The view is fully confirmed by the effects of anthelmintic treatment. Sir Andrew Clark has advanced the opinion that the anæmia of young girls is due to fecal retention leading to reabsorption of ptomaines or other excrementitial products.—*British Medical Journal.*

THE FUTURE OF MEDICAL GRADUATES.—Of some one thousand graduates from collegiate institutions, seventy-five only make for themselves a name and prominence in their calling. About two hundred, having business qualifications, become rich by their practice, and by judicious investments. Four hundred abandon, in whole or part, their profession, for some more lucrative business, and the balance struggle with mediocre ability for a bare subsistence, and a wearying effort to keep up an appearance before the people.—*Pacific Record.*

The Late Dr. Adams C. Hoffman.—At the regular quarterly meeting of the District Medical Society for the County of Hudson, held in Jersey City, N. J., December 6, 1887, the following preamble and resolutions were unanimously adopted:

Whereas, It has pleased an All-wise Providence to remove our brother and co-worker, Dr. Adams C. Hoffman, from the scene of his earthly labors; therefore, be it

Resolved, That while we bow with humble submission to the will of the Most High, we feel more the loss of a sincere friend and a competent physician;

Resolved, That this Society tender its heartfelt sympathies to the relatives and friends of the deceased in this their sad affliction;

Resolved, That a copy of these resolutions be presented to the bereaved family, and that each of the city papers, and The Medical Record and the New York *Medical Journal*, be furnished a copy for publication.

I. N. Quimby, M.D.,
F. D. Gray,
Committee.

The Hypnotic Action of Antipyrin.—Dr. Edward Stubbert, of Bloomfield, N. J., writes: "Within the past few weeks I have noticed two or three articles in The Record, the authors of which refer to the hypnotic effects of antipyrin as something before unknown. In The Medical Record of May 21, 1887, page 579, is an article, over my signature, entitled "The Hypnotic Effects of Antipyrin." I believe that my paper is the first published upon the question, and if the different correspondents referred to will consult it they will learn that for some time I have used the drug as an hypnotic in the place of morphine."

Gonorrhœa and Sterility.—Dr. R. W. Smith, of Xenia, Ind., writes: "In a recent issue of The Medical Record I notice an article on 'Gonorrhœa and Sterility,' by Dr. Wm. Goodell, in which the writer says that he cannot recall a case where a woman bore a child after she had suffered from gonorrhœa. I do not claim to have had a very extensive experience in those matters, but I can recall a number of instances in which both parents were treated by me for gonorrhœa, and in which afterward the wife gave birth to healthy children, who have never manifested any signs of disease. Unless the disease has affected the ovaries there is certainly nothing to prevent conception."

Ricord's Religion.—Hon. Chas. Gayarre, in a most interesting address delivered before the N. O. Medical and Surgical Association, gives many amusing reminiscences of his acquaintance with European medical celebrities of many years ago. Mr. Gayarre has been an invalid, it appears, for somewhat over sixty years, but is still able to speak well of the Faculty. Among others, he formed a friendship for Ricord, and tells the following curious story of him: Ricord was a professed materialist, and rather delighted in asserting or arguing over his views. His immense *salons* were always full, from noon till six, of patients awaiting to see him. They were admitted in turn, and he was unapproachable during these hours except to suffering humanity. As a proof of his regard he had kindly exempted me from the rule. One day when I had something to communicate to him without delay, I called at the time I knew him to be engaged. "Pierre," I said to the servant who was in attendance, "carry my card to your master. I must have access to him without being seen by the crowd of invalids, who might complain of preference granted to me if I were admitted before those who preceded me here." He returned after a few minutes and said: "I will conduct you, according to the doctor's instructions, to his bed-chamber, which can be reached through a secret passage. There you will please to wait until I am permitted to take you to his office." Ricord, at the time, was a bachelor, and I believe has never married. What was my astonishment, when I entered a very large bedroom, of which the walls, from the high ceilings to the floor, were covered with none but magnificent oil paintings, representing sacred subjects. At the head of the bed was a sculptured oak *prie-dieu*, on which there was a superbly illustrated copy of the Gospels that was lying open. There was a red velvet cushion to kneel on at the foot of the *prie-dieu*, surmounted by a beautifully carved ivory Christ on a gilded cross. After a little while I was led to the presence of the medical philosopher, who habitually seemed to delight in being a cynical unbeliever. Guessing at what had passed in my mind, he said with a laugh, not unmixed, I thought, with some embarrassment of manner: "You are surprised, are you not?" "Certainly," I replied; "who would not? Faith, my first impression was that I had been introduced by mistake into the bed-chamber of the Archbishop of Paris." "Well, well, my friend," he said, in a half-jocose and half-serious tone, "I hear and see so many unclean things during the day that, on retiring at night, I like, before going to sleep, to refresh my eyes by looking round my room on holy objects."

Pemphigus Cured by Small-Pox.—Professor Schrötter, of Vienna, relates the following: A young woman, suffering from the chronic form of this disease, had been treated by Hebra, Neumann, and Kaposi for years with varying ill success. During a comparatively free interval, when she was well enough to be an out-patient, she was attacked with laryngeal dyspnœa, and Hebra sent her to Schrötter. The latter discovered pemphigus blebs on the larynx. Two months later she was quite recovered of her pemphigus, and has so continued up to this day. And why? asks the professor. Because she caught variola, and this destroyed the pemphigus.—*Birming. Med. Review.*

A Doctor who Doesn't like Medical Meetings.—The *Indianapolis Sentinel* quotes Dr. E. F. Hodges as follows: "I don't care much about attending medical meetings. Oftentimes they make me very weary, and I don't wonder that newspaper men dislike to report them. A physician may learn a great many things at these meetings, and also out of medical books, but good common-sense and a close observation of the various phases of the disease with which a doctor's patient is afflicted, goes a greater ways." The *Indianapolis Evening News*, next day, says: "Dr. Hodges has a big round head when he says it makes him weary to attend medical societies."

The Treatment of Diphtheria.—Dr. T. E. Hall, of Zanesboro', Minn., writes: "Many articles have appeared in the journals lately on diphtheria, and as I have had some little experience (thirteen years), allow me to say that I have used hyposulphite of soda and tannic acid, in combination, with very great benefit. What the chemical resultant of the combination is I do not know, but I do know that the results are excellent."

The Tincture of Hyoscyamus, in doses of from three to five drops, or one drop of the fluid extract, in combination with triticum repens, made up in the form of a hot tea, is an admirable remedy in cases of irritability of the bladder, with fugitive neuralgic pains about the abdomen and in the lumbar region.—*Dr. J. Aulde.*

A Case of Poisoning from the use of a dose of an ounce of oil of gaultheria is reported in the *Boston Medical and Surgical Journal*. A young woman took the oil for the purpose of inducing a miscarriage, and died some fifteen hours later with symptoms of narcosis and extreme irritation of the gastro-intestinal canal. Poisoning from this drug is rare, although it has been used to a considerable extent lately in the treatment of rheumatism.

The Medical Record

Original Articles.

THE ANNIVERSARY ADDRESS BEFORE THE MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Delivered at Albany, February 7, 1888.

By ALFRED L. LOOMIS, M.D., President.

Gentlemen: I desire this evening to invite attention to the following problems, which are to-day engaging the attention of the profession, and for which it is asking solutions:

1. The relation of microbes to disease processes.
2. Inoculation as a means of modifying or preventing disease.
3. The causes of abnormal temperatures in disease.
4. The effects of antipyretics in the treatment of disease.

Every generation of medical workers have had their special theories and supposed discoveries, to test, to accept, or discard; but never before has the field of medical investigation been so extensive, the workers so many and able, and the methods of research so varied.

It may be interesting, as well as instructive, by way of introduction, to sketch briefly some of the methods of investigation which in different ages have held the profession, and compare them with the methods of to-day. Before instituting any comparison, however, it is but just to recognize that all knowledge is of slow growth, and that the law of development applies to mind as well as to matter; we condemn methods and means because they have been tried and found wanting, and not because of personal superiority of intellect. Nineteenth-century intellectuality must own its indebtedness to mistakes and failures which antedate the birth of Christ.

In every science results are reliable and valuable in direct ratio not only to the accuracy with which deductions are made from given data, but also to the methods of reasoning, the truthfulness of postulates, or supposed facts, and the recognition of all the relations which may exist among determined facts under varying conditions.

No one can deny to the father of medicine equal ability with himself, even while criticising and condemning many of his arguments, based upon well observed facts. He argued from but a few of the many correlated symptoms of any disease, in entire ignorance of all its primary pathological changes, and erected a system of medicine on the basis of his own observation. The earlier periods of medical history present themselves as curiosities, rather than times which we may fairly criticise or compare with our own; medical investigation so superficial could hardly lay claim to the name of method. With but little anatomical and no pathological knowledge, it is hardly to be wondered at that even the best minds were lost in the wildest forms of speculation.

We recognize most clearly that no one mind alone can advance medical knowledge but by an infinitesimal degree, and even this is the result of a mutual interchange of thought. In ages, then, when strong minds were few, and intercourse most limited, men must needs have been more than human to have accomplished more than the masters did. But ambition outran ability, for long before "ye men of Athens spent their days in hearing and telling some new thing," the same search for ultimate facts had been going on, and human minds, impatient of meagre results gained through the hard logic of facts, easily drifted into the limitless sea of theory, and quickly lost sight of the lard of truth and possibility. To speak more exactly, the deductions of theories from few and isolated facts, and the construction of entire systems of medicine upon a single and often unproved assumption, is characteristic of the earlier ages of medicine. By how much is the medical mind different to-day? Under greater restraints, by reason of sharper criticism, and with broader foundations, no such extensive speculative theories are offered for our consideration as mark the earlier history of medicine; but the same spirit remains as one of the heaviest clogs to the advancement of true medical knowledge.

When theoretical conclusions are put forth as established facts, and not as questions demanding experimental answers, then modern medicine is not only turning back to the darkness of earlier ages, but it is putting a stumbling-block for the feet of those who follow.

There is no better test of the scientific mind than its power in deciding, after any given demonstration, between legitimate corollary and unfounded inference.

In no direction, perhaps, has medicine made greater advances in the last quarter of a century than in this; give us facts not fancies—proofs, not propositions—is the demand of the medical mind of to-day; it is digested facts which nourish thought, not crude ones.

The empiricism of the Alexandrian school is perhaps the earliest system of medicine founded on a scientific basis, and offers the fairest points for comparison with the scientific empiricism of to-day. In this school anatomical and physiological investigations were recognized as essential to a thorough knowledge of disease. There was, however, a marked failure to recognize the necessity of determining the changes that were produced in organs and tissues by disease, and to connect morbid conditions with symptoms; histological pathology was an impossibility without instruments of greater precision, and even gross pathology received no attention. Such a failure to appreciate the evident results of pathological processes is the more remarkable in a school which did more than all others of ancient times to advance medical knowledge.

Under the shadows of the granite hills of New Hampshire, on the banks of the Connecticut, the last resting-place of one of the fathers of New England medicine is marked by a small white stone, having only this inscription, "The Disciple of no Man." It is not alone the description of that man, it is the key-note of modern medicine, and symbolizes one of the grandest changes which has ever revolutionized any science.

For nearly a thousand years the history of medicine may be traced by a few names. Schools were founded on men, not principles, until loyalty to one's master, the founder of a school, was stronger than loyalty to truth; and it was doubtless better both for medical science and the patient that the multitude were content to be led, and that between masters and pupils such relations should have existed. But that such a condition of affairs should have continued so long after the "period of letters" in Europe, is a cause for astonishment.

Even as late as the sixteenth century, Galen and Aristotle, and the Arabic authorities, were teachers of medicine throughout the civilized world.

When Ambrose Paré, defying the traditions of more than ten centuries, and the teachings of all authorities, took the bold step of tying an artery, he became the embodiment of that individuality and scientific scepticism which to-day are among the most striking characteristics of medical men—an individuality which thinks and decides for itself—a scepticism which doubts not for the sake of doubting, but because it has too often leaned on broken reeds, too often placed its trust in authority, only to find it like the apples of Sodom—a scepticism which demands proofs and counter-proofs, which scans faces, not men, and learns to recognize truth, whether offered from the wilds of the new world, or the literary storehouses of the old. As a legitimate result of this spirit there has been developed what is without question the greatest advance in methods ever made in medical science. It is the step which has made medicine truly scientific. From the crumbling ruins of abstruse theories and the wrecks of individual systems, overthrown by honest scepticism, comes the recognition of the fact that man is not an accident of undetermined forces—the one thing in all the grand scale, from worlds to worms, that is without plan or not subject to law—but rather the crowning glory of Infinite Wisdom, a machine of marvellous intricacy, yet subject to and obeying the laws of his being with the same certainty as the sun holds his attendant planets in their unchanging way. And what has been the result? The medical world has started afresh at the very rudiments of the science. It has taken its primer, and in the kindergarten of the laboratory it is seeking to know the laws of life and health, and the causes of disease. It has gone far beyond what antiquity ever dreamed. It has developed the empiricism of the Alexandrians, and curbed the philosophy of the Greek. It is seeking to unite scientific empiricism, with equally scientific theory, into one perfect whole; to have all theories based upon clearly determined facts, and to use such theories only as guides to the discovery of the next link in the chain which shall some day bind in eternal subjection the bacillus that walketh by day, and the coccus that rageth by night. When the medical history of the nineteenth century shall be written, it will be that of the laboratory, and the names which the twentieth century will honor are the names of those who have devoted their lives to establishing the unchanging laws of both health and disease which govern this infinitely complex machine, which Infinite Power has made in his own image.

Our first problem for discussion is, *the relation of microbes to disease-processes.*

In looking over the field of bacteriological research for the past ten years, one is struck by the continuous, painstaking investigation of a vast number of observers. Never before has there been so little theorizing with so much work, and the facts which have finally been accepted are such as have come to light only after a long series of carefully made and oft-repeated experiments. One investigator makes a statement; immediately, in a dozen different countries, and by hundreds of observers, his experiments are repeated, his statement of facts proved or disproved, and his conclusions accepted or discarded. The results which have been reached in so short a period prove the wisdom of Agassiz's principle, "That science suffers by every diversion of the energy of scientists which tends to substitute premature theorizing for continuous investigation."

It is not my purpose to consider the biology of the different varieties of bacteria, the conditions of their life, their susceptibility to be influenced by temperature, by the different media in which they grow, nor yet, in turn, how they act and react upon each other, and upon the substances which have nourished them. It must suffice merely to touch upon the practical questions presented by such studies. The life-history of some forms of bacteria have been very thoroughly worked out, but the majority have been as yet imperfectly studied. On account of their universality and their peculiar vital properties, the question which most interests us as practising physicians is, May not these microbes have the power of originating and controlling many of the morbid processes which take place in disease? When we consider the millions of microbes by which we are constantly surrounded; that the soil beneath us and the air around us are laden with them; that they enter the body in the very air we breathe, the food we eat, the water we drink, and yet their influence is baneful only under certain conditions; that it is even possible for men to live in an atmosphere and surroundings which are laden with the most pernicious forms of bacterial life, and yet be perfectly well—the question comes to us, Why is this? If this question is ever answered, it will not be until we have a fuller knowledge of the conditions of life and the inherent properties of even the most carefully studied varieties of bacterial life; nor until we are able to trace more fully the cause and manner of their disappearance after they have gained an entrance into the healthy organism which is able to resist their invasion. It may be regarded as demonstrated that when certain pathogenic microbes have gained entrance into the body and reached localities which afford certain conditions for their development they multiply and form colonies, but what these conditions are is not definitely determined. For example, if a mass containing different varieties of bacteria is introduced into an animal, some will find a suitable soil and multiply, others will die; while if a similiar mass is introduced into an animal of a different species, those bacteria which develop in the first animal will perish in the second. As the bacterial colonies enlarge or multiply they invade the surrounding tissue-cells, and in time produce degeneration and necrosis of the affected part. As a result of the disturbance of the circulation the walls of the blood-vessels are weakened and the microbes gain entrance to the blood-current. In a similar manner the lymphatics are invaded. If the blood or lymph offers conditions suitable for their growth they multiply rapidly, otherwise they perish. Their death is supposed by some to be due to the special action of the white corpuscles. Some bacteria flourish best in blood which is flowing, as the bacillus anthrax; others, as the tubercle bacillus, in blood at rest; and still others only multiply rapidly in the lymph, as the micrococcus of erysipelas. Conveyed by the blood or lymph the bacteria lodge in different organs, and there start secondary changes similar to those which have taken place at the primary seat of invasion; this is well illustrated in animals that have been inoculated with pure culture of tubercle. In this connection three questions naturally present themselves:

1. Are organisms present in all morbid processes?
2. Can they originate *de novo*, and is there a mutability of the bacteria?
3. And by far the most important question: Do microbes act as invariable and sole causes of disease, or are they the result of pathological processes instituted in their absence?

In answer to the first question, Are organisms present in all morbid processes? it may be stated that it is to-day claimed that specific micro-organisms have been demonstrated in the following diseases: Splenic fever, relapsing fever, erysipelas, tuberculosis, cholera, pneumonia, malarial fevers, small-pox, scarlet fever, measles, diphtheria, typhoid and typhus fevers, pyæmia, leprosy, acute rheumatism, ulcerative endocarditis, pyelitis, gonorrhœa, acute atrophy of the liver, and in a number of skin diseases, as herpes, sycosis, etc. And it is claimed that our inability to discover them in other diseases is no proof of their absence, for their minute size and peculiar reaction to staining agents render their demonstration very difficult, and as yet we have no general method by which we are able to recognize the spores of these organisms, which are known to be more resistant than the micro-organisms themselves. Again, our examinations may be made in the advanced stage of the disease processes, when all traces of bacteria may have disappeared, for it has been shown by experiments upon animals that by the time that tissue-changes occasioned by bacteria are complete, they themselves have disappeared. Not until our technique is more perfect can we say positively that bacteria may not be found in all diseases, especially infectious and contagious ones.

In answer to the question, Can bacteria originate *de novo*, and is there a mutability of the bacteria? it may be stated that no reliable evidence has as yet been deduced to show that microbes can originate spontaneously. The experiments of Lister and Pasteur prove almost conclusively that it is impossible for them to originate spontaneously. Koch, from his culture-experiments, concludes that one form of bacteria cannot change into another form, that micrococci can never become bacilli, nor can the innocuous varieties, by any change in the conditions of their life, become noxious. Although many observers, such as Nagel, Davine, and Buchues dispute this, still, at the present time, the weight of evidence is with Koch. There is no doubt that the properties possessed by different bacteria may be modified, increased, or diminished by changes in their external conditions; at one time they are more infectious than at another, but never do they acquire attributes differing from those possessed by the variety to which they belong. Even in bacteria there is a struggle for existence; the micrococci may be thrust aside by the bacilli.

Our third question is more difficult to answer than either of the others, viz., Are microbes the cause or effects of disease? If they can be proved to be the cause, then their presence is of the greatest importance; while if they are only the effect, our interest in them, from a medical stand-point, ceases. What, then, is the precise significance of their coexistence with diseased processes? The facts which seem to be established at the present time are as follows: Pasteur having proved by his vital theory that bacteria are the cause of all fermentation and putrefaction, students in, and believers of, the germ-theory of disease, noticing the close relation these fermentative and putrefactive processes bear to communicable diseases, reasoned by analogy that they likewise must be of bacterial origin. After carrying on a long series of experiments, such as inoculating animals with pure cultures of various species of bacteria, it was demonstrated that in some of the specific diseases bacteria are developed, and that the same micro-organism is always present in the same disease, and that these organisms could be transferred from animal to animal without changing their characteristic form—their specific physiological action—and without the presence, at any time, of any other form of bacteria. Therefore it was inferred that not only are these diseases of bacterial origin, but that each disease is developed only from its own micro-organism, recognizable under the microscope by its size and shape, its staining properties, peculiarities of growth in nutrient media, and, as has recently been demonstrated, by its chemical reaction. For example, during the past year Koch has shown that the tubular bacillus, the comma bacillus or cholera nostras, which is considered by many as identical with his comma bacillus of Asiatic cholera, can be differentiated from it, not by its size and shape, but by its reaction to nitric acid; for, by adding nitric acid to a growth of the cholera bacillus, a very characteristic red color is produced, while no reaction whatever is shown on the culture of the tubular bacillus. Thus advances are being made every day which lessen the elements of uncertainty. In this connection it must be noted that we do not as yet know why different animals behave so differently toward infectious agents; still less can we account for differences in their susceptibility, for an experimenter soon learns that there is a marked difference among the lower animals as to the degree and manner in which they are affected by microbes. One form will flourish in one species and not in another—rats are unaffected by the anthrax bacillus, while mice readily succumb to their invasions. Even among animals of the same species there is a marked difference of susceptibility to the infectious diseases, and most of the animals upon which experiments have been made are subject to but few of the diseases of man. The power of resisting inoculation is evidently far less in animals than in man; it is therefore reasoning from false premises to say that the action of microbes upon animals is the same as upon man.

While a reasonable conjecture may be reached regarding the bacterial origin of infectious diseases by our experiments upon animals, positive proof can be obtained only by studying the action of their microbes upon the human body. The only diseases in which a bacterial origin has been completely demonstrated in man are erysipelas, and splenic and relapsing fever. The proof that the tubercle bacillus is the cause of tuberculosis requires yet the crucial test of human inoculation. The explanation of the action of bacteria in disease, as given by Professor Zeigler, seems to me the most comprehensive and satisfactory which has yet been given. He says, "The factors which determine the invasion and the course of the development of bacteria within the human body are two: 1. The bacteria must be endowed with certain vital properties of a special kind. 2. There must be a certain predisposition to favor their development on the part of the system." For example, one with no phthisical predisposition, either inherited or acquired, may live in an atmosphere laden with tubercle bacilli and never develop phthisis; while one with strong phthisical predisposition, under the same conditions, furnishes a fit soil for the growth of the bacilli, and quickly succumbs to their invasion. This factor of predisposition is the important one in the problem. What it really consists in is as yet undetermined. Probably it is due to some alteration of the tissues. Often we can see what this alteration is, such as a local wound, a disturbance of the circulation, etc.; but in the majority of instances the anatomical basis of this change is an unknown quantity which is yet to be worked out. When found, then, the cycle of proof will be complete. The simple demonstration of the presence of the tubercle bacilli in phthisical processes and in the sputum is of great practical value in the early diagnosis of phthisis, but it does not determine the relationship that exists between the bacillus and the phthisical processes. We must not lose sight of the possibility that it is only after the physico-chemical constituents of the tissues have been morbidly altered, by a yet unknown agent, that the conditions are such as to allow of the growth and colonization of the different pathogenic microbes. If, in time, it shall be conclusively proved that microbes alone, or microbes plus some as yet unknown quantity, are the cause of disease processes, we can readily appreciate the great importance of the knowledge which is to-day being gained by bacteriological studies, and we may hope in the near future to be able to discover the microbes of each disease, and to destroy them, or render them harmless, and so combat early the development of many diseases that at present we are unable to control.

I will now pass to the consideration of our next problem, viz.: *Inoculation as a means of modifying or preventing disease.* This problem has been strongly brought before the profession by Pasteur's recent experiments in hydrophobia. The protection afforded by vaccination against small-pox, not only by granting immunity from the disease, but by modifying its severity when it is developed, brought first before the world the practical advantages of inoculation. The next great discovery in this direction was made by Pasteur, who found that by the prolonged culture of the anthrax bacillus, at a temperature of 42° or 43° C., and with exposure to the oxygen of the air, the virulence of the organisms decreased

Animals inoculated with the attenuated virus developed only a mild type of splenic fever, and after recovery were found to be incapable of again developing the disease, even when inoculated with virus of full strength. After repeated inoculations with attenuated virus, Pasteur found that inoculated sheep were quite unaffected by injections of a pure culture of the bacillus. A practical application of this discovery has since been made by agriculturists throughout Europe. Toussant, by cultivating the bacteria of chicken-cholera, found that each successive generation was less virulent than the preceding, and that this attenuated virus, when introduced into animals, produced a severe local lesion with but slight constitutional disturbance, and that after recovery the inoculated animals were exempt from the infection for a year or more, after which time a second inoculation was necessary. More recently, Koch has proved the immunity afforded by inoculation in another disease known as the septicæmia of mice. If a rabbit be inoculated with septicæmic blood, it will die within seventy hours; but if a weakened culture of the septicæmic bacteria be introduced into the tip of a rabbit's ear, the animal will only suffer from the local effects of the virus, and afterward will not be affected by repeated inoculations of the strongest culture. Koch also showed that such immunity could not be conferred by inoculation with attenuated virus in all infectious diseases; for instance, relapsing fever can be produced again and again in the same animals after inoculation. Experimenters, more recently, from these and other results obtained by inoculating animals with attenuated bacteria of different infectious diseases, have sought to furnish proof that similar inoculations in man would be followed by similar immunities.

The fact that individuals who have once passed through certain infectious diseases, or a mitigated form of them, are afterward not susceptible to the infection of these diseases, may be regarded as a strong evidence of the possibilities of such immunities being obtained by inoculation with the attenuated viruses of infectious diseases. While working in this line Pasteur brought forward the results of his inoculations against hydrophobia. Both his experiments and his results have aroused adverse criticism from those whose ignorance of the subject forbade any fair discussion of his methods or conclusions, as well as by those who presumably were competent to sit in judgment upon him; as a consequence the profession has been slow to accept his conclusions.

It would seem, however, that the report of the English Commission appointed by Parliament to investigate the subject, composed as it was of the best English observers, must at once put at rest all doubts. This report is all the more interesting and valuable because it is the first that has been made by impartial and competent authority upon Pasteur's work. The report of the Commission declares that it is certain that Pasteur has discovered a method of protection against hydrophobia comparable to that given by vaccination against smallpox; and in their opinion it is "difficult to overestimate the importance of the discovery;" and that while not every case which he has treated has escaped, yet a large proportion of cases have been absolutely cured. The report of such a commission will not only give to Pasteur's researches and experiments an authority which they have not before had, but it will also give an impetus to similar investigations in other directions, for a method of inoculation is presented by his experiments by which it may be possible to prevent other diseases in man. The diseases which up to the present time have been proved to be preventable by inoculation are vaccinia, variola, splenic fever, and, if we regard the report of the English Commission as conclusive, hydrophobia. All the explanations that have been given of the immunity afforded by inoculation are unsatisfactory, and at best only conjectural. It seems possible that a person who survives an infectious disease has in his struggle with it acquired the power of resisting such infection by some as yet unknown modification in the chemical constituents of his tissues, and that acquired immunity from inoculation is on the basis of the introduction of an infection in minute quantities until such a chemical change has been reached; but all such explanations are only suggestive. While it has been proved that inoculation is protective in a few diseases, it is reasonable to infer, in those diseases in which one attack is protective against a second, that preventive inoculation is possible, and it opens a wide field for investigation and experimentation.

The causes of abnormal temperature in disease is the third problem to which I invite attention. What is fever, is a question that still remains unanswered, and which is constantly pressing itself upon the clinical observer for solution. Few subjects have been more at the mercy of theorists, or been made more the sport of ingenious minds. In discussing it we are primarily led to a consideration of the animal heat of normal conditions. It is comparatively easy to reach reasonable and, indeed, demonstrable conclusions on the physiology of this subject up to a certain point. Beyond this we are confronted with difficulties which, with our present means, we are unable to solve with any approach to success or satisfaction. In regard to the causation of a certain amount of manifest energy in the form of heat, as exhibited in the body of animals, there appears to be no reasonable objection to the view that conditions which result in the manifestation of such energy outside the body shall exhibit similar calorific effects within the tissues. It is well established that foods exhibit their heat potential in the changes incident to the production of water and carbon dioxide, and these demonstrations of chemical force are true combustions, and yield stored heat just as certainly as when like changes occur apart from the living tissues.

In the light of present physiology it appears almost self-evident that the prominent factor of heat production exists in metabolism, and that metabolic processes consist in the liberation of heat stored in the food introduced into the body. The inadequacy of these changes alone to account for the maintenance of an equable temperature of the body during the extraordinary and varying conditions of man's environment also seems apparent.

Very early in the investigation of this subject one becomes conscious of the imperative necessity for the existence of some regulating mechanism. I must, however, say just here, that I have never been able to convince myself, from analogy or otherwise, of the necessity for a nervous mechanism which shall give rise to heat-production without corresponding chemical changes, either general or local. Such a theory, to my mind, calls for effects without a cause. I cannot, in other words, conceive of any reasonable evidence against the view that physical processes must be governed by the same laws, and be productive of the same results, in every instance and under all conditions.

This brings us squarely to the question, Is the hyperpyrexia of fever an extraordinary manifestation of animal heat, governed and controlled always by the same mechanisms, differing only in degree; or are the conditions other than those of simple pyrexia, requiring special mechanisms for its development? In the study of the literature of this subject we find that increased calorific manifestations, resulting from an exaggerated body-metabolism, was for a long period deemed a reasonable explanation of the temperature of fever. This view was based upon the fact that food and tissues represent a certain and definite potential; that in the metabolic processes this is exhibited as kinetic energy in the form of heat. Later, these changes were found to be under certain nervous control, and special mechanisms were demonstrated as regulating metabolism, without offering any objection to the combustion theory of animal heat and of fever as well. Within a comparatively recent period the theory has been advanced that pyrexia results from a disturbance of the normal equilibrium between the production and the dissipation of heat.

The views advanced by Maclagan and others on this subject are essentially as follows: First, that in the ordinary production of animal heat the influence of the nervous system is neither essential nor exhibited, even though the pyrexia be considerable. Second, that as soon as the disturbance induced by fever occurs, or the normal balance between heat-production and heat-dissipation is reached, nervous mechanisms are called into requisition, and hyperpyrexia results. Third, that the contagium of fever consumes the proteids designed for tissue-repair.

It has been pretty conclusively shown by the experiments of Dr. Wood that an inhibitory control—a check—is in constant supervision over ordinary heat-production, and he has located, with more or less definiteness, a cerebral heat-centre, the normal inhibitory action of which is reflexly withdrawn in fever, and the resulting increased metabolism is exhibited in increased temperature. Dr. Wood has performed many carefully conducted experiments on animals in the settlement of the question, "Does fever consist in an increase of heat-dissipation from the body, or in an increased heat-production?" It is difficult to understand just how the body can continue to dissipate heat for any prolonged period without a corresponding heat-production.

Thus far experimental physiology has proved an efficient help in determining the mechanism of fever; but all attempts to isolate the spirit which primarily actuates these mechanisms have left us groping for an agency which we have thus far found too subtle for recognition.

What causes the peripheral stimulus which Dr. Ordt and others believe is carried to the spinal thermogenetic centres, and there translated into influences which are transmitted to the tissues, to increase or diminish those transformations upon which depend the amount of heat produced? What is this morbific principle which so influences the cerebro-spinal centres of Brodie, Hetzig, Eulenburg, Landois, Wood, and others, as to inhibit their action on the heat-reservoirs of the tissues by increasing chemical metamorphosis? Such questions as these force us back to the original proposition, What is fever? One must plainly see the futility of attempts to answer this question until some more satisfactory definition can be given than that fever is an exhibition of phenomena or symptoms, of which high temperature is the most prominent. Fever is a something which we have not yet grasped, which produces those symptoms or *effects* which we have been accustomed to regard as its *cause*. Beyond this we actually know nothing, except that the result of its presence is manifested largely, at least, through the nervous apparatus; and knowing so little of its nature, its causes must be speculative. What is destined to come out of the work in the direction in which the medical world is now active, remains to be seen.

The establishment of a special nervous control over heat-production will unquestionably remain an important and leading idea in the physiology of pyrexia, at least. The disposition evinced by various observers, to regard the febrile conditions as produced by a specific cause—one entirely distinct and apart from normal phenomena—has not, as yet, modified in any very essential degree the views entertained by clinicians of the earlier part of the present century. Unsatisfactory and incapable as the chemical theory is in accounting for certain temperature-manifestations, it must remain the leading and influencing thought upon this subject until something essentially and radically different from that afforded by the results of present experimenters has been suggested.

We may sum up our knowledge on this subject as follows:

1. Chemical transformations produce definite results, whether occurring within the tissues or outside the body.
2. The body takes cognizance of the potential of food, and during certain changes, which are true combustions, a definite, unalterable value is exhibited as kinetic energy in the form of heat.
3. Muscular action is an insignificant factor in the establishment of animal heat, excepting as it excites metabolic energy.
4. The varying circumstances of man's environment necessitate some heat-regulating mechanism to preserve the conditions of homogenesis.
5. The evidence of the existence of a regulating mechanism, operating independently of chemical change, is insufficient.
6. There appears to be no reason for regarding the increased heat production of fever as requiring mechanisms other than those acting in normal rise in temperature.
7. While anatomical difficulties interfere with the complete isolation of such ganglia, the existence of two cerebral inhibiting heat-mechanisms has been fairly established; as much may be said of like spinal ganglia.
8. The production of heat in fever is in exact consonance with metabolism, and the chemical changes are under the control of the heat-mechanisms through the connection between the nervous and the vascular apparatus.
9. In the present state of our knowledge we can only theorize as to the identity of the material in the circulating media of the body which institutes the primary irritation in febrile conditions. That it is inconstant in composition or nature, there is abundant reason for believing. That it is microbic in every instance, I am unprepared to admit. We certainly must have a clearer idea of what fever is, before we accept or seek to explore the action of poisons or microbes in producing it. We are too prone to seek for the causes of phenomena before we have determined the precise nature of the phenomena themselves. It is evident that the bacterial pathology, which is dominating all the teachings and investigations of the present day, has, as yet, given us no clew to an explanation of the causes and phenomena of fever.

The length of time already occupied in this discussion will compel me to be brief in my consideration of our last problem, viz., *The effects of antipyretics in the treatment of disease.*

During the last decade, since the thermometer has become a part of the physician's *armamentarium*, antipyretics have taken a more prominent place in the treatment of disease than ever before, probably for the reason that by it we are able to more readily and accurately determine their effects upon the body-temperature. If we accept the view that high temperatures cause destructive metamorphosis of tissue—a view which, in some unaccountable way, has gained almost universal acceptance—the importance of reducing high body-temperatures in all diseases cannot be overestimated, and we are justified in resorting to the most powerful antipyretic agents to accomplish it. But there is very little, if any, evidence that a febrile temperature of 106° or 107° F. causes any serious injury to the body—certainly that no such dangerous destructive changes take place in the blood and solid organs as we have been led to suppose from the writings of Continental observers. I can find no clinical or experimental evidence to sustain the popular doctrine of Liebermeister and others, that the grave symptoms in fever—the symptoms that usually render a prognosis unfavorable—are referable to a high temperature-range. In fact, the evidences of the so-called parenchymatous changes, and of the grave febrile symptoms in acute infectious diseases, are as well marked, and as often present, in cases where the temperature-range at no time reaches 103° F. as in those cases which are attended by very high temperature. In a series of cases of typhoid fever of low temperature, often subnormal, which have come under my observation during the past year, in which the ratio of mortality was unusually high, I was surprised at the development of so many of those very grave symptoms which I have been accustomed to regard as due to the effects of high ranges of temperature; from these and similar observations in other acute diseases, I have come to the opinion that there is no necessary relationship between the other febrile symptoms and the temperature-range.

It is evident that we have passed through the period of enthusiasm in the antipyretic treatment of disease, and already prominent workers have come seriously to consider whether the dangers of hyperpyrexia have not been overestimated, and the question is being asked, May not the high temperature in disease, especially in infectious diseases, be a conservative process? From statements already made it is evident that elevation of temperature is far from being all that there is to fever.

A pertinent question for every practitioner of medicine to put to himself is, How much has he accomplished by the use of antipyretics in the arrest and safer conduct of disease, and are there no dangers attending their employment? Whatever answer may be given to these questions, I am convinced that the heroic use of antipyretic measures, which within the past few years has come into such general use—the one idea of the modern therapeutist being to reduce temperature at all hazards—has a side of danger that should not be lost sight of. If the temperature-range in a case of fever or pneumonia is about 105° or 106° F., and can readily be reduced by mild antipyretic measures, the condition of the patient at the same time being made more comfortable by their use, I should most certainly recommend their employment. But when powerful antipyretic measures are required to effect temperature-reduction, and its reduction is only temporary, I question very much their beneficial effects; in fact, I am quite confident that such reductions are obtained only by an expenditure of vital force on the part of the patient which largely diminishes his chances of ultimate recovery, especially if the hyperpyrexia has been long continued, for I have frequently noticed that their daily employment for a prolonged period has been followed by grave nervous phenomena and the evidence of the most extreme cardiac failure, greater than could have been caused by the high temperature alone. I think no one whose experience is at all extensive in the use of antipyretics in the treatment of acute infectious diseases will for a moment claim that they have any power in shortening their duration or greatly modifying their severity. Time will not allow me to enter into a detailed account of the different antipyretics now in use, to compare their relative merits, nor to theorize as to their mode of action. In a general way they may be divided into two classes—the application of cold to the surface, and the internal administration of antipyretic drugs. The mode of action of the two classes is evidently not the same, although they may both effect the reduction of temperature. Whether they act by diminishing heat-production, or by increasing heat-dissipation, is still undetermined; for every day's experience teaches that sometimes when antipyretic drugs act badly or inefficiently, cold applied to the surface, in the form of baths or packs, often accomplishes the desired results in the most satisfactory way, and *vice versa.* It has seemed to me that the beneficial action of antipyrine and antifebrine is not so much due to their power of controlling temperature as to their tranquillizing effects upon the nervous system. Dr. Wood, from his experiments on animals, concludes that antipyrine diminishes heat-production and heat-dissipation, and that its action on the bodily heat is entirely independent of any influence on the circulation—that it probably acts through the nervous system directly upon the chemical movements of the organism.

Clinical experience has taught me that opium is often one of our most efficient and reliable antipyretics. The old custom of administering Dover's powder in small doses at stated intervals, throughout the course of a typhoid fever, undoubtedly had its origin in the power of opium to control temperature by its tranquillizing effects upon the nervous system. As all discussions in this line must at present be theoretical and unsatisfactory, I close the consideration of this problem with the practical question: If temperature-reduction does not shorten the duration, mitigate the severity, or avert serious complication in disease, and if the ratio of mortality is not so diminished as to encourage us that we are making advances by antipyretic measures, on *what basis are we justified in their use?* Evidently, only on the basis that by their use we relieve one of the many phenomena of fever. If this can be accomplished without serious loss of vitality, or at the expense of the reserved force of the patient, we are justified in their use; but do not let us imagine that by reducing temperature we are controlling fever.

In review of the subjects which I have brought to your notice this evening, it is evident that the work of to-day is gradually rescuing medicine from the realm of wilful and unreasonable speculation, and is establishing it on a basis of new facts. Yet I would warn those who are in haste to elevate the experimental above the practical, that the experimental will never alone be able to accomplish the great work that is ever before the practical physician. We cannot safely forsake the rich storehouse of clinical observations that have been gathered by so many master-minds, and withdraw into the recesses of the laboratory; for although in the work of the laboratory we hope to find the solution of many of the problems with which we are now struggling, it must be remembered that the special field of medical investigation is, and ever will be, the study of disease in its activities. Experimental work, even in the study of the causes of disease, must always be one-sided; the whole number of its causes can only be studied and understood at the bedside of the patient. The great treasures of clinical observations must ever be the basis of true medical advancement. It is here that medicine is to find her firm and enduring foundations. Let us then labor without rest, in the laboratory, at the bedside, and in the dead-house, for the solution of the great and vital problems that are before us in every branch of our science, and the full benefit of our labors later generations will come to know and enjoy.

Digitalis in Aortic Disease.—In the Therapeutical Section of the British Medical Association at the Dublin meeting, Dr. Sansom, of London, read a paper upon the treatment of some forms of aortic disease. In cases of aortic disease without cardiac symptoms, it might be laid down as an absolute rule that all agents which tended to increase the force of the ventricular systole are absolutely hurtful. Compensation being already perfect, such agents could only serve to disturb the equilibrium. As regards the very important question of the administration of digitalis in aortic disease, medical opinion and experience had varied much from time to time. The present tendency was rather in favor of its administration, a view supported by Dr. Oliver, of Newcastle-on-Tyne. While carefully guarding himself against an absolute expression of opinion, Dr. Sansom pointed out certain drawbacks to the use of digitalis. These are: 1. It may increase the distress and aggravate the symptoms present. In some of his cases where digitalis had had this effect, he had seen great relief follow the administration of five-minim doses of tincture of aconite and the inhalation of nitrite of amyl. 2. Digitalis sometimes caused sickness. 3. In some cases where much temporary relief was obtained by its administration, sudden death had followed apparently as the result of its use. Yet, in spite of these dangers and drawbacks, he believed that digitalis was sometimes of service in the *early* stage of aortic disease and for a *limited* time. If given in the same manner and for the same length of time as was usual in mitral disease, great evil would result.—*The Practitioner*, November, 1887.

ON THE TECHNIQUE OF THE OPERATIONS FOR THE RELIEF OF INTESTINAL OBSTRUCTION.[1]

BY ROBERT F. WEIR, M.D.,

PROFESSOR OF CLINICAL SURGERY IN THE COLLEGE OF PHYSICIANS AND SURGEONS, ETC., NEW YORK.

WHETHER a simple enterotomy or the more severe laparotomy should be resorted to, in a case of intestinal obstruction, depends largely upon a correct appreciation of the strength of the patient. It is becoming more and more properly recognized that exhaustion in these and kindred abdominal lesions proceeds with rapidity, and is generally due to septic influences acting under the most favorable conditions. Though a laparotomy be scientifically the correct procedure, yet in many instances its performance does not save, but promptly terminates the life of the patient; while the resort to enterotomy, which is admitted to be a blind opening of a piece of distended intestine, presumably above the site of the obstruction, yields not infrequently a brilliant result. It, however, does not belong to me to discuss this portion of the subject; my assigned duty is to dwell upon, in the short time allotted to me, the various steps of the operative technique.

Let me therefore ask your attention, first, to some points common to both of these operations. Although it is possible that the section of the peritoneum after the division of the abdominal wall may reveal that an adhesive or a suppurative peritonitis is present, and therefore that an infectious condition already exists, yet, as this may not be found, it is imperative, before any operative interference with the abdominal cavity is begun, that the rules of antiseptic surgery should be strictly followed in the preparation of the hands of the surgeon and his assistants, as well as of the instruments, ligatures, sponges, and towels—in short, of everything that may be carried into the wound during the operation. The belly-wall, and particularly that sink-hole, the umbilicus, should be thoroughly cleansed by brushing with soap and hot water, and then washed with either alcohol or a 1 to 20 carbolic, or a 1 to 1,000 sublimate solution. If time will permit, it is advisable to keep one of these fluids in contact with the skin for several hours prior to the operation, under oiled silk, rubber-cloth, or other impermeable tissue. Now as to the anæsthetic—naturally an American surgeon would prefer ether for this purpose. Such, too, is yet my conviction for the ordinary operations in general and abdominal surgery, and such has been, until recently, my custom, even in laparotomy performed for intestinal obstruction, perforation of the intestines, and similar grave conditions. But in the weakened condition of the patient requiring an operation in these circumstances, I have been led, from experience, to choose chloroform for the production of anæsthesia, since with ether I have found the cyanosis and bronchorrhœa alarmingly marked and decidedly depressing. I say all this, knowing two things, one of which is universally conceded, that, as a general thing, chloroform is more dangerous than ether. The second, however, is not so well known. It is, that ether is more unsafe than has been and is now supposed, for, out of 12,000 operations which I have collected from the records of the New York Hospital, there were 6 deaths from this latter anæsthetic. With chloroform administered, largely diluted with air, which is best accomplished with an Esmarch's inhaler, in a recent case of laparotomy for a perforated appendix, the color and respiration of the patient were everything that was to be desired.

Cocaine has been suggested to obviate the risks of both ether and chloroform; but this in a laparotomy, while permitting the painless cutting through the abdominal walls, will not insure the quietude that is necessary in handling, treating, and replacing the intestines. It might, however, be applicable to the slighter operation of enterotomy. Before the anæsthetic is given, to strengthen the patient's heart it is also of service to administer, hypodermatically, $\frac{1}{100}$ to $\frac{1}{80}$ of atropia, and to introduce a large rectal enema of brandy, say from two to four ounces. The patient's bladder should also be emptied, voluntarily, if possible.

Enterotomy.—For the performance of this operation, according to Schede,[1] an incision not exceeding two and one-half inches in length is made in the right iliac region, above and parallel to the outer half of Poupart's ligament. The peritoneum, when cut through, is sutured all around the wound, with a continued catgut suture, to the skin. This shuts off the muscular and cellular planes from subsequent infection, and also affords a broader surface for the prompt adhesion of the loop of intestine, after it has been fastened into this opening. Then the first presenting loop of *distended* intestine is seized, and also sutured, by a continued catgut suture, to the prepared abdominal wound, the needle including only the serous and muscular coats, but not the mucous membrane. A space of intestine about one and one-half inch long, and three-fourths of an inch broad, is thus fixed to the belly-wall. An opening in the bowel sufficient to admit the forefinger is now made, and while the finger is *in situ* two silk sutures, each with its own needle, are passed from the bowel through the adjacent wall of the abdominal wound and tied. This sufficiently secures the patency of the completed artificial anus. Only in exceptional cases is it permitted to delay the opening of the intestine for twenty-four or forty-eight hours, and thus to obtain greater security against leakage into the peritoneal cavity.

A loose protective antiseptic dressing is then applied, and frequently changed, care being taken not to choke up the fecal opening. This operation, originally devised by Nélaton, is based on the anatomical fact that the presenting loop is usually found low enough down the intestinal canal not to interfere with the subsequent nourishment of the patient, and its distended state is a reasonable evidence of its being above the site of the obstruction.

Laparotomy.—The uncertainties which environ a surgeon throughout the whole subject of intestinal obstruction follow him even when he stands, knife in hand, over his anæsthetized patient. Where and how shall he make his incision are questions that must be decided, and considerable argument can be brought to support the various plans of action proposed. Where a decided swelling, as, for instance, a plainly recognized invagination, or a fairly well-marked tumor exists, surgeons are in accord that the incision is to be chosen as nearly over the point to be attacked as may be practicable. But with the nature and situation of the obstruction unknown, a median laparotomy is also conceded to be the most advisable section. But here, however, comes in the points of controversy. Shall it be a moderate incision, as is resorted to in an ordinary ovariotomy, *i.e.*, from two and one-half to five inches long, or shall a heroic section of seven to twelve inches be made?

Let me state the *pros* and *cons*, for they are of real importance. The selection depends, actually, whether the surgeon should resort to one of two methods of discovering the cause of the obstruction. Shall he, by a small incision, just sufficiently large to admit his hand, and yet limited enough to permit the distended intestines being kept within the abdomen by this plugging, or by the aid of his assistants, make his preliminary examination by touch in the regions most likely to be the site of an obstruction, such as, first, the cæcum and adjacent parts, where invaginations, abscesses, bands, and diverticula, are most commonly met with, and then continue his search, by sweeping over the natural openings in the abdominal wall, where perhaps a concealed or partial hernia may be present? Or, failing to find the source of the obstruction, shall he further blindly move his hand about the intestines, hoping to discover a tumor or a stricture, or some satisfactory cause for the occluded intestine? I beg here to say, in a general criticism of these proceedings, that among a mass of intestines the touch is very fallible, and that, from personal experience, the recognition of a distended cæcum, which is a landmark of importance, is extremely difficult even when the obstruction is below this point. For be it remembered that, usually, above the obstruction the fæces are in a liquid condition, more or less mixed with gases, and have no distinctive sensation. I have myself found so little help from such explorations, save concerning herniæ and large tumors, that I cannot advise resort to it, except to the most limited degree. What else can be done with a short incision, even though enlarged beyond the point of admitting the hand? If the assistants seize the edges of the wound and draw them apart and strongly forward, and at the same time the intestines be kept back, the operator may, perhaps, determine two things which may greatly help him. He may, perhaps, fortunately see—and generally in the pelvis—a mass of shrunken intestines, which are also much paler than the overlying or adjacent loops. If he should strike such a bonanza as this, his work is much simplified; he has only to raise up a portion of this collapsed intestine, intrust a loop of it to one of his assistants to hold in an angle of the wound, and then to follow the bowel along until the obstruction is reached; each few inches, as he goes along in this examination, is, after its inspection, tucked under the belly-wall on the opposite side of the wound out of the way. Should he find on coming, say, to the ileocæcal valve, that he is travelling away from the obstruction, he goes back to the loop still held by his assistant, and works his way similarly upward.[1] But suppose he does not have this good fortune of finding the collapsed bowel, for possibly the obstruction may be quite near the cæcum, how may he proceed? The suggestion has been made,[2] and it is a good one, as I can testify, that a moment's inspection of the several loops of intestine that first present themselves to view will show that some of them are much more congested, are much darker, than others are, and it is possible, in many cases, also to see of a certain congested loop that it is of a deeper hue toward one part than it is a few inches farther off. Follow, then, as in the preceding case, toward the more congested portion, and it will often lead to the obstruction. Occasionally, too, when but moderate inflation of the bowels is encountered, it is possible to crowd and hold back the intestines by forcing in large sponges and thus secure a view of the cæcal or sigmoidal regions. It would seem from this, to a tyro, to be an easy task to discover, and perhaps relieve, the cause of an intestinal occlusion. Unhappily, it is only occasionally that the conditions are as simple as these. It is more than likely, in the presence of distended bowels, that, failing any guide, the surgeon may be compelled to venture on the weary way of tracing the small intestine upward and downward its whole length, in the manner just indicated—an attempt which will probably be rendered nugatory by the repeated escape of distended portions of the bowels, or by the slipping of loops from his fingers and their being then confounded with other indistinguishable intestine; or by the losing the landmark loop from between the assistant's fingers, though this may sometimes be better secured by tying a band of iodoform gauze with long ends around it, or by perforating the mesentery at a thin place where vessels are not to be seen the intestine can be similarly loosely tied, and thus the accident be prevented, and the wound rid of crowding fingers. Much time may be spent in this way in keeping in and replacing the bowels, and the treatment of the distended intestines becomes therefore of paramount importance in a laparotomy for obstruction. Two ways of any reliance are given to overcome this hindrance to the rapid completion of the operation.

---

[1] Read at the meeting of the State Medical Society at Albany, N.Y., on February 9, 1888, as a part of the discussion on Intestinal Obstruction.

[1] Beiträge zur Chirurgischen Behandlung des Ileus, Arch. f. klin. Chirurg., Bd xxxvi., S. 635.

One may puncture or incise the intestine, and thus let out the gas and fluid fæces, and so permit an easier manipulation and search in the abdominal cavity, and also a readier reposition and retention when the time comes to close the wound. But punctures made in a tense and paralyzed intestine, even with a small needle, frequently leak. Hutchinson, of London, demonstrated this, and I can myself confirm by a personal experience the correctness of the observation. It is better to use, if a collapsed condition of the bowels is determined upon, the safer incision of an inch long in the axis of the bowels, having first drawn out a loop before making the section sufficiently far, to prevent the fluid fæces getting into the peritoneal cavity. This is aided by plugging at the same time the abdominal wound with sponges. Madelung[1] further advises that, after emptying as much as possible the intestines of their contents, the wound should be carefully sewn up with the usual Czerny-Lembert sutures, and returned temporarily to the abdominal cavity, having been first provisionally cut off from the pressure of fresh intestinal contents, and from the possible traction of the surgeon's efforts, by encircling the coil of intestine containing the incision by thread, or by what has in other conditions proved serviceable to me, by strands of iodoform gauze passed through the mesentery and around the bowel above and below the wound. This incision can be afterward used if required to make an artificial anus.

The second way to manage the disadvantages accruing from the greatly distended bowels is not to try to diminish their size, but to remove them bodily from the field of search and operation. This is often done by the surgeon from necessity, but it is wiser to do it from choice. The following has therefore, in a laparotomy, seemed to me the more reasonable procedure to follow: After the often fruitless but proper palpation of the cæcum and the usual hernial openings, and a similar attempt to recognize by sight or touch a collapsed knuckle of intestine, the protruding loops of intestine should be rapidly drawn out of the wound until a large portion of the small intestines are outside the peritoneal cavity. They should be received into a large sponge,[2] or towels wrung out of warm water previously boiled, or a warm solution of salicylic acid—1 to 1,000—and to a special assistant their care should be assigned. It should be his sole business to prevent undue traction upon their mesenteric attachments. This is a point of importance, for I have seen, for want of this precaution, the mesenteric peritoneum badly torn, and veins lying deep in the peritoneal cavity ruptured. From time to time, while thus out of the peritoneal cavity, warm water, plain or medicated, should be poured over the extruded intestines. By this procedure the cavity of the abdomen can be readily inspected and quickly examined with the eye or with the hand. That such thorough examination is required is borne out by the fact that more than one, or even two, causes of obstruction are sometimes met with. I have to report, myself, one fatal case, where only one band was recognized and removed, and the autopsy showed that a second existed.

If nothing is found in the intestines themselves, as they are withdrawn, to account for the obstruction, nor in the region of the abdomen opposite to the side upon which they rested, they can be turned over to the other side of the abdominal wound, and the previously hidden side of the abdomen thus exposed to view for examination. By this means, and this means only, can the large as well as the small intestines be rapidly and thoroughly explored. By this means only, also, can the rarer causes of obstruction be detected, such as cysts of the pancreas, hernia through Treitz's fossa, etc. The necessary corollary to this evisceration is a decidedly ample incision. This should reach upward certainly as far as the umbilicus, and I should say that in many cases it should go an inch or two beyond this point. Kümmel,[1] of Hamburg, advises a heroic incision from the ensiform cartilage to the pubis, and gives seven instances in which he has employed this long division of the abdominal walls, with two successes. He states that in all of his cases the source of the obstruction was found in a few minutes.

---

[1] Rand, of Liverpool (British Medical Journal, December 22, 1883), has said that the direction of the root of the mesenteric fold will determine whether one is proceeding toward the stomach or toward the cæcum, but this has proved of no practical value, though anatomically correct.

[2] Greig Smith, in his Abdominal Surgery, p. 376, says it has only failed once in eight cases in which he operated.

[1] Zur Frage der operativen Behandlung der inneren Darmeinklemmungen, Arch. f. klin. Chir., Bd. xxxvi., S. 283.

[2] Dr Hunter, of the New York Woman's Hospital, has utilized the ordinary Henis vegetable-squeezer in expediting the handling of such sponges.

Without proceeding to this extremity, it is undoubtedly true that the sound rule of surgery obtains in the abdominal cavity, as well as elsewhere, viz., that the hand should always be controlled by the eye. Treves, of London, however, has expressed himself decidedly adverse to this method of taking out the intestines, and believes that the procedure previously spoken of, of loop by loop examination, is to be chosen for action in the search for an obstruction. Five years ago I was of the same opinion, but careful observation of such cases of laparotomy for intestinal obstruction, six in number, as have occurred in my own charge, and also of those that have come under my notice in the practice of my colleagues, have forced upon me the conviction that not only is more time consumed by the older plan, but that by the prolonged manipulation of the hand in the abdominal cavity more exhaustion of the patient's force is brought about than by the freer incision and removal of intestines.

Leaving for a few moments the consideration of the treatment of the cause of obstruction, after it has been found, by either of these two plans, I beg to continue the consideration of this subject of the management of the distended intestines. Not only do they, as has already been remarked, interfere with the search for the obstruction, but they are a serious obstacle to the final closure of the wound when this becomes necessary. Anyone who has seen this attempted will realize the fact that the bowels, in the endeavor to replace and keep them in the abdominal cavity, are subjected to no little violence, which is often appreciably demonstrated by the blood that oozes from the minute ruptures of their peritoneal covering. Indeed, during the progress of an operation they seem to be much more distended, and often actually do become so, than they were at its beginning, and the closure of the wound offers the surgeon many times more difficulty than any other portion of the operation. This very difficulty of replacing the intestine has been one of the strong points urged against a large incision. Rehn,[2] of Frankfort, has, however, brought to our notice a procedure which offers help in this direction. He has found that the washing out of the stomach, after Kussmaul's method, diminishes the intestinal contents very materially, and he has resorted to this plan during the process of laparotomy with even better results than when it had been employed prior to the operation. The distended intestines are in this way satisfactorily diminished in size, and can be easily replaced in the abdominal cavity, and readily retained there. Should this expedient—which though tested but a few times yet in each instance has proved to work happily—should this, I say, not act well, the sewing up of the wound is best accomplished according to the method lately set forth by Kümmel, and which has been followed by Czerny and others.

This device is a simple one, and is carried out in the following manner: A properly disinfected and warm wet towel is placed over the whole mass of protruding intestines. It is then tucked in on all sides, as far as possible, through the wound and under the parietal peritoneum. Now, the intestines at the upper end of the wound are pressed inward, and one suture, carried through the skin, muscle, and peritoneum, is passed and secured. A further tucking in and additional pressure upon the intestines is now made. The latter are in this way protected from violence by the towel, and, at the same time, more satisfactorily controlled than by the naked hand or hands of the assistants. After three or four sutures have been applied the included portion of the towel is partially withdrawn from above, and the wound is further closed, and so on until the last suture is placed *in situ*.

It must be here understood that the plan of sewing together, first, the divided peritoneum, and then the skin, muscles, and fascia, as is done in ordinary ovariotomy, cannot be practised in cases where the intestines are much distended. In fact, it is often impossible to bring together at all the cut peritoneal surfaces in a satisfactory manner. This peritoneal gap in the abdominal wall is, however, of no especial moment, for the intestines rest up against it, and shut off in a short time the general peritoneum, as I have demonstrated in two instances; once in the living subject, where my abdominal wound gave way, without permanent detriment, and once at an autopsy.

Let me now recur to the treatment of the causes of obstruction after such have been found. If a band, or a peritoneal adhesion, or an omental cord should be detected, and if it is too large to be easily ruptured with the finger, it is advisable, in order to prevent a recurrence of the obstruction, to tie it with two ligatures and to cut it off close to its origin. Similarly, if there should be an opening in the mesentery, through which a loop of intestine is caught, after the latter has been relieved the opening should be sewn up with catgut or fine silk sutures. Should the knotting or intertwining of the intestines through such an opening in the mesentery be so intricate that it cannot be disentangled, and such things have happened, then the example of Reali[1] may be followed. This surgeon was compelled to cut the intestine in two, which permitted its loosening. He then sewed the divided ends together, and success followed the procedure. It has since been repeated by Kümmel in a similar instance.

If a diverticulum of the intestine adherent at its tip has produced the obstruction, it becomes a question as to its removal, after the intestine has been liberated from its grasp. It is better, I think, to cut it off after ligating it, but leaving enough beyond the ligature to allow its peritoneal coat to be separately sutured with Lembert's sutures over its divided muscular and mucous coats.

Should the obstruction be due to a gall-stone of large size, this—and the same remark applies to intestinal calculi and foreign bodies—can be removed by an incision, to be subsequently closed, or there can be first tried the expedient suggested by Tait,[2] of passing a needle from below through the intestinal wall, and in this manner breaking up the gall-stone, which, as is well known, is quite friable. It may sometimes be pushed along through the ileo-cæcal valve into the large intestines, and there left; or it may be also moved into a sound portion of the bowel and then crushed with well-padded forceps—as had been done in the biliary passages. Again, should an invaginated condition of the bowel be found, its reduction is usually accomplished by slight traction made upon its upper and lower ends. This, however, may not suffice, and Rydygier[3] advises pushing from below and pulling from above, a proceeding which Hutchinson,[4] of London, had substantially practised in 1874. He also aids the reduction by carrying his finger between the invaginating and the invaginated portions of the intestine.

[4] Med. Chir. Trans., 1874, p. 31.

Should the reduction of the intussusception be found to be impossible, or should the invaginated tumor be found to be in a state of gangrene, three courses are open to the surgeon. If the mass is not too large, it can be resected and the divided ends of the intestine sewn together, or it can be resected and the divided ends brought out to a convenient point in the wound and there fastened, for the formation of a temporary artificial anus; or if the invaginated intestine is of too great a size to be resected [1]—though over a metre has several times been excised with success and without subsequent impairment of nutrition—the intestine above the invagination can be fastened into the wound and an artificial anus made in it.

Roser,[2] of Marbourg, in order to avoid the tendency which sometimes exists in invagination to recur, proposes, after it has been reduced, to suture the loosened invaginated parts to the belly-wall at two or three points. This has also been applied to volvulus of the intestine.

If the obstruction should be found to be due to a tumor, whether of the large or small intestine, and it is more commonly found in the large intestine, the formation of an artificial anus should be resorted to. In exceptional instances, such as in growths not capable of removal, or in irreducible invaginations, then the expedient suggested by Mynther and Senn,[3] of Milwaukee, of making an opening between the intestine above and below the obstructing portion, can be entertained. The ingenious plates of the latter surgeon, now exhibited, for the rapid accomplishment of this operation of enterostomy, by pressing together large peritoneal surfaces adjacent to the openings in the intestine, seem worthy of trial.

Finally, the making of an artificial anus is also indicated if the occlusion of the bowel should be brought about by the pressure of a neoplasm originating outside of the intestines. It is, however, contraindicated where the obstruction is high up in the small intestine, when the risks of a resection must be taken; also, it cannot be always applied to the fixed portions of the large bowel, and it may be then necessary to do a colotomy after closing the laparotomy-incision.

In all the foregoing instances in which the cause of the obstruction could not be safely removed, it will be noticed that an artificial anus is advised to be made. This is based on sound surgical observation. Not only is it a quicker procedure than a resection, but, in the exhausting conditions such as are now under consideration, it is immeasurably safer. In a series of thirty-five resections of the large intestines which I collected together the mortality of resections, undertaken when symptoms of obstruction demanded laparotomy, amounted to one hundred per cent. Reichel also shows that in the small intestine resections with obstruction gave seventy-five per cent. of mortality, whereas in secondary resections for an artificial anus the mortality is lessened to thirty-seven per cent., which is corroborated by Makins [4] in his report of 15 deaths in 39 resections for artificial anus. The rule for its performance varies but little from that given for an enterotomy except when it is necessary to resect a portion of the intestine. Here the precaution should be taken to bring the part of the intestine well out of the abdominal cavity, and then, having first made a slight cut into the bowel, to allow the free escape of gas and liquid fæces, and thus to diminish the size of the intestine, a ligature of silk or iodoform gauze is secured at each end, just beyond the place where the section of the bowel is to be made, somewhat after the previously described method of Madelung. However, the fingers of an expert assistant will often suffice for this purpose.

The portion of the intestine to be resected is then cut out, together with a small V-shaped piece of the mesentery. After ligating the bleeding points and after sewing together the divided mesentery (the removal of which materially facilitates the subsequent cure of the artificial anus) the open ends of the bowel are either plugged securely with sponges, or, better still, are temporarily but tightly closed with sutures. The constricting bands of iodoform gauze are then removed, and the closed bowel-ends are thoroughly fastened to each other and to the abdominal wound, the peritoneal layer of which is first to be secured to the skin, as is done in Nélaton's enterotomy. If a sufficient relief has been afforded by the outflow of the intestinal contents to warrant the continuation of the closure of the end of the upper bowel for twenty-four hours, this will contribute somewhat to the patient's safety. Hahn has recommended, to preserve the advantages of a clean wound and yet to allow of escape of fæces, that the intestine should be closed tightly around a rubber tube, which is left projecting some distance for this purpose. It is well also to let the ends of the intestine project a little beyond the skin, for sometimes it will be found that by the necessary interference with the mesentery a slight necrosis at the line of the section of the bowel will take place. This was noticed by me in one case where an artificial anus was made after a resection of the large intestine.

If a resection with a reunion of the divided ends of the intestine should be determined upon, the advice of Kraussold,[1] which has been lately revived by Senn,[2] should be kept in mind. These suggest that a portion of omentum, either partially or totally separated, should be wrapped around the line of the intestinal suture. This speedily adheres, and aids in obviating the risk of fecal extravasation from a defective suture. A similar strip of peritoneum can also be obtained from the removed portion of mesentery and used singly or doubled on itself. It is also desirable, when such a resection and reunion of intestine has been practicable, to place the newly united bowel near to the line of the wound just before the latter is closed, and also to carry, according to my judgment, a drainage tube through the wound down to this place. I am not, for want of time, able to give further reference to the methods of applying sutures to the divided intestines in such an operation, and must refer you to other sources for this information.

In all the preceding directions concerning the details of the various operative procedures upon the sources of obstruction, it has been assumed that the surgeon has been able to avoid the entrance of fæces and blood into the abdominal cavity, and that for the final cleansing of this cavity, prior to the closing of the wound, the so-called toilet of the peritoneum may be confined to a simple sponging out of the pelvis and dorsal gutters with soft, warm sponges.

There is, however, a different state of affairs that may be unexpectedly met with. The first incision into the peritoneal cavity may reveal the fact that suppurative peritonitis exists. This cannot always be readily determined beforehand. It is most commonly found associated with perforation of the intestines, either at the appendix vermiformis or elsewhere. Duplay,[3] of Paris, was among the first to call attention to the fact that in such cases the symptoms of obstruction, even to fecal vomiting, were strongly present. In thirteen cases that I have recently gathered together of laparotomy for perforation of the appendix vermiformis, it was found that symptoms of intestinal obstruction existed in six cases, and caused a resort to the operation without the diagnosis of perforation having been previously made. Its insidious progress and defective symptoms often cause delay to a most dangerous point. The recently advised hypodermatic puncture of the abdominal walls in other places than in the right iliac fossa will sometimes give an early clew to the nature of the disorder. Such punctures, made after urination, deep into the pelvis,[1] or from the rectum [2] upward, are most likely to be successful in withdrawing pus, which is formed in perforative peritonitis with great rapidity. Should, therefore, a suppurative peritonitis be recognized on entering the abdominal cavity by a laparotomy, the surgeon should at once make a thorough examination *by sight* of the region of the appendix vermiformis. Failing that, the intestinal tract must be explored as before directed, and the opening, if found, closed by Lembert sutures; or if the perforation is recognized in the appendix, this latter should be tied above the opening and the distal portion cut off. As the stump is too short to secure a proper covering by its own peritoneal coat, it must be either left exposed or covered with the adjacent peritoneum by one or two stitches. In this instance, and in many others where peritonitis exists to a decided extent, the peritoneal cavity must be cleansed in a more thorough manner than by the simple introduction of sponges. It should be washed out several times by large quantities of warm water that has previously been boiled, or, as Mikulicz [3] has advised, after extended experimentation on animals, with a solution of salicylic acid of the strength of 1 to 1,000 of water. This is found to be potent and safe. This observer found that in washing out an abdominal cavity in which infectious peritonitis had been induced by him in animals, first with a six per cent. solution of common salt, then with a salicylic solution, he was enabled to save sixty per cent. of the animals experimented upon. Solutions of carbolic acid and corrosive sublimate, even when largely diluted, are too poisonous to be used in this manner. It is self-evident that in this condition of suppurative peritonitis drainage must be employed, preferably with two tubes, one going to the site of the perforation, possibly through a separate opening in the belly, and the other to the depth of the pelvis, through the median abdominal opening.

[3] Archives Générales de Médecine, November, 1876.

The after-treatment of patients that have been operated upon by laparotomy is of considerable importance, and varies remarkably from that which has been used ten years ago. Opium is abstained from as much as possible. Liquids are given not at all, or only in the most sparing manner for the first twenty-four or forty-eight hours. If vomiting occurs, more than should be expected from the anæsthetic, or if the distention is not promptly removed by the action of the bowels, or if symptoms of peritonitis present themselves, you should not hesitate to follow the suggestion of Tait and administer a saline purge. Surgeons have long been acquainted with the fact that, after a herniotomy, for instance, although it was known that the obstruction had been removed, the bowels remained distended from paralysis of the part above the site of the strangulation. This paralytic condition, from over-distention or from deranged innervation, is also one of the objections raised against the performance, in conditions of obstruction, of a resection and reunion of the divided ends of the bowel, even if the strength of the patient admitted this operative procedure. The interesting report of Mr. Malcolm, of London, has within the last few months given us a clear demonstration, not only of the reasons for this purgative treatment, but also of its efficacy, and of its limitations. This is a paper well worthy of perusal to all interested in operations in the abdominal cavity. It is published in *The Lancet* of October 29, 1887.

Lastly, in concluding this imperfect and somewhat diffuse account of the various surgical manœuvres demanded in the treatment of intestinal obstruction, I feel that I am warranted in somewhat departing from the rule that has been laid down for me, of *ne sutor ultra crepidam*, and this I do, from an earnest desire to join with my colleagues in this discussion, in the entreaty that an early surgical interference be resorted to in these very destructive cases, and I also conceive it wise to urge upon the profession, not as some have done, that every case of this description should be from the beginning placed in the hands of the surgeon, for this is not generally practicable, but that from the very inception of such cases the surgeon should be associated with the physician in the care of the patient. This harmony of action and conjoined supervision will, I believe, obviate the delays and clear up the doubts which are now too often solved by time rather than by the knife.

ACUTE BRIGHT'S DISEASE.[1]

By FRANCIS DELAFIELD, M.D.,

NEW YORK.

The literature of Bright's disease is already voluminous: systematic treatises, monographs, records of cases and of pathological examinations, are numerous, and yet our knowledge of the subject is imperfect, confused, and unsatisfactory.

This is due in part to the inherent difficulties of the subject, in part to faulty methods of investigation. The kidneys have been looked at too much by themselves, and too little as if they were only a part of the whole body. If from inflammation, or from other causes, we find the pleural or the peritoneal cavity filled with the blood-serum, we call the fluid serum; but if the same conditions exist in the kidneys, and we find the serum in the urine, we call it albumen. If a patient with scarlatina has an endocarditis, we call it a complicating inflammation; if he has a nephritis, we say that this is due to the elimination of the poison of the disease by the kidneys. And so there has always been the same disposition to think too much of the functions of the kidneys, and too little of their structure. The tendency has been to consider the diseases of the kidneys by themselves, apart from those of the rest of the body, and to accumulate descriptions of kidney lesions without bringing them into an orderly classification.

So descriptions and names have been multiplied, assertions and counter-assertions have increased, and no definite or systematic knowledge of the diseases of the kidneys has resulted.

While this condition of affairs is an embarrassment and a hindrance to the practitioner, it presses with double weight on those who have both to practise medicine and to teach it.

It is now for many years that I have studied patients during life, and kidneys after death; that I have read all the available literature on the subject; that I have written and lectured concerning it; but always with the same feeling of dissatisfaction and want of success.

During the past three years I have made another effort. I have gone over afresh all the clinical and pathological material of previous years, and it is because I feel that, for the first time, I stand on a surer footing than ever before, that I venture to bring to your notice a subject concerning which so much has already been said.

In doing this I confine myself entirely to the subject of acute Bright's disease, leaving aside for the present everything relative to the chronic form.

At the very beginning of an attempt to study the lesions of the kidneys, we are embarrassed by the absence of a general agreement as to what lesions, in any part of the body, are to be considered of an inflammatory nature. The only changes which are universally accepted as inflammatory are those which belong to exudative inflammation.

When in any part of the body there is an accumulation of blood in the vessels, an exudation of blood-plasma, an emigration of white blood-cells, a diapedesis of red blood-cells, everyone calls this an inflammatory process, and the serum, fibrine, and pus are clearly inflammatory products. But even in this best-defined form of inflammation it is not generally understood that the production of serum, fibrine, and pus are compatible with the absence of visible structural changes in the inflamed tissues after death. The presence or absence of such changes depends upon the severity of the inflammation, and the facility with which the inflammatory products can escape from the position in which they first make their appearance.

---

[1] Read at the Meeting of the Medical Society of New York, at Albany, February 8, 1888.

When we come to the changes in the cells of the viscera, and to the formation of new connective tissue, there is no longer any agreement. Some ascribe such changes to inflammation, others to degeneration.

But, no matter how we account for these changes, or whether we call them inflammatory or degenerative, we find that they constitute an important feature in the diseases of the viscera.

The changes we find in the cells are: A simple swelling of the cells, a disposition to degeneration and necrosis, and a formation of new cells to take the place of those destroyed. With such changes in the cells is generally associated some degree of exudative inflammation; very often this is but slight, with only the exudation of a little serum; occasionally it is severe, and serum, fibrine, and pus are found as inflammatory products.

Such changes in the viscera may be termed "parenchymatous" or "cellular" inflammation or degeneration.

The formation of new connective tissue in the viscera takes place in their stroma. Here we find diffuse or circumscribed formations of ordinary connective tissue, or of the same tissue with an excess of round cells. This may be called "interstitial" inflammation, or degeneration.

Still further, we may find that, in the viscera, there exist at the same time the evidences of exudative inflammation, a growth of new connective tissue in the stroma, and marked changes in the cells. To designate this process we may employ the term "diffuse" inflammation.

Now, if we turn to the kidneys we find that, like the other viscera, they are composed of blood-vessels, a stroma, and special cells; and that the only peculiar features about them are the arrangement of some of the blood-vessels into the tufts of the Malpighian bodies, and the distribution of the special cells in tubules.

We have a right, then, to expect that the lesions of the kidneys will correspond to those of other parts of the body, but that the structure of the glomeruli and of the tubes may add something to the character of the inflammation.

A careful study after death of the changes in the kidneys, and of the histories of the patients during life, seems to me to show that this is the case, and that all the examples of acute Bright's disease may be conveniently arranged in three classes:

I. An exudative nephritis, characterized by a congestion of the blood-vessels, an exudation of the blood-plasma, an emigration of white blood-cells, a diapedesis of red blood-cells, and certain changes in the glomeruli.

II. A parenchymatous or cellular inflammation or degeneration, characterized by changes in the renal epithelium.

III. A diffuse nephritis, which involves all the tissues of the kidneys, but of which the most important features are the growth of new connective tissue and the permanent character of the lesions.

I. Acute Exudative Nephritis.—This is an acute inflammation of the kidneys, characterized by congestion, an exudation of plasma, an emigration of white blood cells from the vessels; to which may be added swelling or necrosis of the renal epithelium and changes in the glomeruli.

Of such a nephritis we may distinguish four varieties:

(1) A mild form, which gives symptoms during life, but leaves no lesions in the kidneys after death.

(2) A more severe form, in which we find inflammatory products in the kidneys after death.

(3) A form characterized by the excessive production of pus cells.

(4) A form in which the inflammation is prolonged for an unusual length of time, and effects more extensive changes in the structure of the kidneys.

Lesions.—In a nephritis of this type we should expect that the inflammatory products—the serum, white and red blood-cells, and coagulated matter from the blood-plasma—would collect in the Malpighian bodies and tubes, or infiltrate the stroma between the tubes; and that, of the inflammatory products in the tubes and Malpighian bodies, a part would be discharged with the urine and a part found in the kidneys after death. We should also expect that the quantity of inflammatory products should be in proportion to the severity of the inflammation, and that an excessive number of pus-cells would belong to the especially severe forms of the disease. Still further, it is evident that with the milder examples of nephritis, with but little exudation, no inflammatory products might be found in the kidneys after death, all having been discharged with the urine during life.

As a matter of fact, the kidneys do present just such changes. In the mild cases we find no decided lesions in the kidneys after death. In the more severe cases the kidneys are increased in size, their surfaces are smooth. The cortical portion is thick and white, or white mottled with red, or the entire kidney is intensely congested. If the stroma is infiltrated with serum, the kidney is succulent and wet; if the number of pus-cells is very great, there will be little, whitish foci in the kidney.

The evidences of exudation are most marked in the cortical portion of the kidneys. Here we find tubes containing cast-matter or irregular coagulated matter; and very frequently, in most of the cortex tubes there will also be a flattening of the epithelium and a dilatation of the tubes, as if these had been distended by fluid exudation. Less frequently, the epithelium of some of the convoluted tubes is swollen and broken down. If pus-cells are numerous they will be found in the tubes, the stroma, and Malpighian capsules, and the capillary veins will contain white blood-cells. To these ordinary evidences of exudative inflammation are added changes in the glomeruli, which at first sight seem peculiar, but which are really similar to the changes which we find in the arteries and capillaries in many inflamed tissues.

If we look at a normal glomerulus, we see that it is composed of a tuft of capillary vessels enclosed in a capsule. The capsule is lined with a layer of flat cells continuous with the epithelium of the tubes. The capillary vessels have rather thick walls; on their walls are large nuclei, such as are seen in other capillaries, but it is very difficult to demonstrate in them the endothelial cells which are regularly found in blood-vessels. The outer surfaces of the vessels of the tufts are plastered over with large flat cells, which we can see at the margins of the tufts and between all the vessels which make up the tuft.

In acute exudative nephritis we may find within the glomerular capsules, as within the tubes, coagulated matter or white blood-cells. The capsular epithelium is swollen, sometimes to such an extent that the cells are almost cuboidal instead of flat. The most noticeable changes, however, are in the cells which cover the outer surfaces of the blood-vessels of the tufts. These cells are swollen, or they are both swollen and multiplied. In addition there may be changes within these vessels. They may be filled with white blood-cells, or the nuclei in their walls are swollen and surrounded by protoplasm.

As a result of these changes in the glomerular epithelium, we find the tufts swollen and filling, or even distending, the capsules; we can no longer distinguish the different vessels which make up the tufts, as their edges are covered by the swollen cells, and the coils of vessels are all matted together. How much impediment is offered to the passage of the blood through the glomeruli by these changes in them it is not easy to say.

In most cases of exudative nephritis the patients recover, and the glomeruli return to their natural condition; but in the cases which are protracted for months, we find the glomeruli still presenting the same changes which have just been described, or with thickened capsules, or with the tufts in various stages of atrophy and obliteration.

In some examples of exudative nephritis we also find a thickening of the walls of the branches of the renal artery within the kidney. This thickening is due to a swelling of the muscle-cells in the walls of these vessels.

Etiology.—Acute exudative nephritis is frequently a primary disease, either occurring after exposure to cold, or without discoverable cause. It complicates scarlatina, measles, diphtheria, typhoid fever, acute general tuberculosis, pneumonia, acute endocarditis, acute peritonitis, dysentery, erysipelas, diabetes, and many other of the infectious diseases and severe inflammations. It is one of the forms of nephritis which complicate the puerperal condition.

Symptoms.—In the milder cases the only symptoms are the changes in the urine. This is somewhat diminished in quantity, of normal, or high, specific gravity; it contains albumen in moderate quantities, a few casts, sometimes blood.

In the more severe cases, the changes in the urine are more decided. It is diminished in quantity or even suppressed, its specific gravity is normal, or high, or low; the quantity of albumen is very large; the casts are numerous—hyaline, granular, containing white or red blood-cells or epithelium; there are also free white and red blood-cells and epithelial cells from the kidneys and the bladder. As a rule, the quantity of albumen and the number of casts are in proportion to the severity of the nephritis, but this is not always the case. Large quantities of albumen, numerous casts, and many white and red blood-cells may be found in the urine of kidneys which, after death, show no structural changes. While, on the other hand, small quantities of albumen and a few hyaline casts are compatible with a severe nephritis. Still further, the number of casts found in the urine during life is not always in proportion to the number of casts and quantity of coagulated matter found in the corresponding kidneys after death.

In addition to the changes in the quantity and composition of the urine, the patients present constitutional symptoms, which vary in the different cases as to their number and their severity. A febrile movement with more or less prostration, stupor, headache, sleeplessness, restlessness, muscular twitchings and general convulsions, dyspnœa, loss of appetite, nausea and vomiting, a pulse of high tension with exaggerated heart-action, or hypertrophy of the left ventricle, dropsy, and anæmia—these may be called the characteristic symptoms of acute exudative nephritis. Of these symptoms a certain number—the fever, the prostration, the loss of appetite and nausea, the anæmia, the diminution in the quantity of urine—are such as would naturally accompany an acute inflammation of the kidneys, and very often they are the only symptoms which do accompany it.

But with this same kidney lesion a certain number of patients will present, besides the symptoms just mentioned, the additional features of cerebral symptoms, changes in the heart and circulation, and dropsy. We might indeed think that the cerebral symptoms and the dropsy were due to the diminished excretion of urine; but when these conditions occur, as they often do, in patients who are passing large quantities of urine of good specific gravity, and when they are absent, as they often are, in patients who are hardly passing any urine at all, it is evident that these symptoms are not directly due to the nephritis, but constitute a separate, complicating set of symptoms, which may be present or absent in any given case of nephritis.

What the complicating lesion is which produces these symptoms, we do not fully know; but the changes in the action of the heart and the dropsy naturally direct our attention to the arteries and capillaries, with the expectation of finding in them some morbid condition which will hinder the passage of the blood through them. Whether the morbid condition is of an inflammatory nature, or whether it is only a spasmodic contraction, we are as yet ignorant.

The cases of exudative nephritis with an excessive production of pus-cells have a somewhat different clinical history. Such a nephritis occurs both in children and adults; it may be primary, or complicate scarlatina, diphtheria, or measles.

The invasion is sudden, with a high temperature and marked prostration. Restlessness, delirium, headache, and stupor are soon developed and continue throughout the disease. The patients lose flesh and strength and pass into the typhoid state. Dropsy is slight or absent altogether. The urine is not as much diminished in quantity as one would expect, its specific gravity is not changed; albumen, casts, and red and white blood-cells are present in considerable quantities, but not always early in the disease.

It is a very fatal form of nephritis, and yet one easily misunderstood on account of the resemblance of its symptoms to those of an acute meningitis.

As a rule, exudative nephritis is a temporary disease, resulting either in the death of the patient or in recovery, with a return of the kidney to its natural condition. But there are exceptions to this rule.

Either after one or more acute attacks, or after a subacute invasion, the nephritis may take on a chronic form.

The patients then give the same history as that which belongs to a diffuse nephritis. They go on for months and years exhibiting renal symptoms, either continuously or with intermissions.

When they die, it is found that in addition to the ordinary lesions of exudative nephritis there are added a diffuse thickening of the stroma of the cortex, with more or less degeneration of the epithelial cells.

II. PARENCHYMATOUS INFLAMMATION, OR DEGENERATION OF THE KIDNEYS.—I employ this term to designate all the acute morbid processes which seem to belong to the epithelium of the tubes and of the Malpighian capsules, and in which all the evidences of disease are confined entirely to these cells, or are secondary to the changes in them.

Such acute changes are a frequent complication of the infectious disease, of severe inflammations, and of extensive injuries; they are also found after poisoning with phosphorus, arsenic, and mercury.

After death the gross appearance of the kidneys varies with the intensity of the morbid process, and with the presence or absence of secondary changes on the part of the blood-vessels. In the milder cases the kidney is a little swollen, and the cortex is pale; in the severe cases the kidney is much enlarged, and the cortex is either white or congested.

The changes in the cells are: A simple swelling of the cell-body, especially of its network, causing it to look larger and more opaque and to take on irregular shapes; an infiltration of the cell-bodies with granules of fat; a death of the cells, which may take the form of coagulation-necrosis, or of a disintegration and crumbling of the cell-bodies; a desquamation of the dead cells; a formation within the tubes of myeline-globules, apparently derived from the epithelium; and a growth of new cells, to take the place of the desquamated epithelium. All these changes are most marked in the convoluted tubes.

In most examples of parenchymatous nephritis no other changes will be found, although the presence of albumen and casts in the urine indicates an exudation. But in the more severe forms, with rapid death of the epithelium, the process is a more stormy one, and the blood-vessels take an active share in the inflammatory process. We find the veins and glomeruli gorged with blood, and in the tubes cast matter, coagulated matter, and blood-cells.

Symptoms.—The urine is diminished in quantity or even suppressed, according to the severity of the lesion. Its specific gravity is unchanged. In most of the cases little or no albumen and few or no casts are found. In the more intense cases, with the addition of the exudative inflammation, albumen in large quantities, numerous casts, red and white blood-cells, and renal epithelium make their appearance in the urine.

So many of the examples of this nephritis are secondary to other diseases and of mild type that they can hardly be said to have any symptoms of their own. The severer forms are indeed dangerous to life, but dropsy, cerebral symptoms, and disturbances of the circulation are not associated with them.

III. ACUTE DIFFUSE NEPHRITIS.—This is the most serious and important of all the forms of acute nephritis, not only for the reason that it involves so many of the structures of the kidney, but because its lesions are from the first of a permanent character, and because disturbances of the circulation are so frequently associated with it.

It is one of the forms of scarlatinal nephritis, it occurs early and late in the course of diphtheria, it is the most important variety of the nephritis of pregnancy, and it is especially frequent as a primary nephritis, with or without a history of exposure to cold.

The changes in the kidneys are extensive and well marked.

The kidneys are large, at first smooth, later sometimes a little roughened; the cortical portion is thick, white, or mottled with yellow or red, or congested; the pyramids are red.

In these kidneys we find the same lesions as have been described as belonging to exudative nephritis, but with two additional changes—changes which are found in the earliest stages of the inflammation, and which give the characteristic stamp to the lesion. First, a growth of connective tissue in the stroma; second, a growth of the capsule-cells of the Malpighian bodies.

Both these changes do not involve the whole of the kidney, but symmetrical strips or wedges in the cortex which follow the line of the arteries. These wedges are small or large, few or numerous, regular or irregular, in the different kidneys. But in every wedge we find the same general characters—one or more arteries of which the walls are thickened. The Malpighian bodies belonging to this artery show an enormous growth of capsule-cells, with compression of the tufts. Running parallel to these arteries there is a growth of connective-tissue cells and basement substance in the stroma. Between the wedges we find at first only the changes of exudative nephritis, later a diffuse growth of connective tissue.

So, if the patient live long enough, the final result is atrophied kidneys, which a careless examination might confound with the atrophied kidneys of chronic Bright's disease, but yet which really differ from them in their origin and their structure.

Symptoms.—The urine during the acute periods of the nephritis is scanty, colored by blood, of high or low specific gravity. It contains much albumen, numerous casts of all kinds, and blood. Exceptionally the casts are few or absent. Later in the disease, or when it is of a more subacute type, the urine is more abundant, the specific gravity falls, the albumen and the casts continue. In the protracted cases the albumen and casts may for a time diminish, or even disappear.

The patients develop all the symptoms which we are accustomed to associate with Bright's disease—headache, restlessness, neuralgic pains, delirium, stupor, coma, muscular twitchings, and general convulsions; dyspnœa and cough; loss of appetite, nausea, and vomiting; neuro-retinitis; diarrhœa; increased arterial tension, and hypertrophy of the left venticle of the heart; anæmia, loss of flesh and strength; and dropsy, often developed to an extreme degree.

The course of the disease varies with the intensity with which it is developed and the rapidity with which it proceeds.

The invasion may be sudden, the symptoms marked, and the duration of the disease short, with a fatal termination. Or, with the same acute invasion, the disease may be protracted over many months. Or, the invasion may be gradual, the course of the disease subacute, the symptoms not continuous, but with periods of improvement or even apparent recovery, and the duration of the disease protracted for months and years.

The prognosis of this form of nephritis is bad. The lesion is a permanent and a progressive one. It is indeed apparently possible to recover from it, although with damaged kidneys, but this is the exception. The rule is, that sooner or later the disease proves fatal, although it may well happen that periods of improvement give rise to false hopes of recovery.

Treatment.—From what has been said concerning the nature of acute Bright's disease, some general conclusions may be drawn as to its treatment.

In that form of the disease characterized by changes in the cells alone, it does not seem probable that any treatment can be of avail. We are not possessed of any means by which we we can affect acute morbid changes in the epithelium of the kidneys.

In exudative nephritis two separate sets of symptoms present themselves to us for treatment—those due to the nephritis, and those due to the complicating disturbances of the circulation. For the nephritis we naturally employ the same methods of treatment which are appropriate to an acute exudative inflammation in any part of the body; for the disturbances of the circulation we use the means by which we can regulate the action of the heart, and put a stop to contraction of the arteries.

In acute diffuse nephritis the problem of treatment becomes much more complicated. The inflammation of the kidneys may be, at the first, of an acute or of a subacute type; the complicated disturbances of the circulation are developed to a great degree; the long continuance of the disease has its effect on the entire nutrition of the patient; the character of the lesion is such that we hope for the alleviation of symptoms, and the prolongation of life, rather than for the cure of the patient.

Now let me ask you to apply this classification of acute Bright's disease to your own cases.

1. You have seen primary cases which gave well-marked renal symptoms for days or weeks, and then recovered completely, with the exception of a few very severe cases which terminated fatally. These were examples of exudative nephritis.

2. With scarlatina and diphtheria, with pneumonia, with typhoid fever, with many of the infectious diseases and of the acute inflammations you have often found albumen and casts in the urine, but no other symptoms. These were examples of mild exudative or of parenchymatous nephritis.

3. You have seen women, in the latter months of pregnancy, with albumen and casts in the urine, sometimes with dropsy, sometimes with cerebral symptoms. You have found that if the patients survive their immediate danger that most of them have no further kidney trouble, but that a few will, later, give the evidences of a chronic nephritis. This means that these patients have suffered from more or less severe forms of exudative nephritis or from diffuse nephritis.

4. You have seen primary cases which began with headache, nausea, anæmia, dropsy, and albumen and casts in the urine, and which then went on for months or years, sometimes better, sometimes worse, until they died of their disease. These patients had diffuse nephritis.

5. You have seen diphtheria or scarlatina followed for months and years by renal symptoms. This again means a diffuse nephritis.

So, no matter what names are used, I believe that we can group all the cases of acute Bright's disease into three classes:

1. One in which the principal share in the morbid process is taken by the blood-vessels, and in which the

principal evidences of the inflammation are the matters exuded from the blood-vessels.

Such a nephritis varies as to its severity and its fatality, but is regularly only a temporary lesion.

2. One in which the principal share in the morbid process is taken by the renal epithelium, and in which the evidences of inflammation are certain changes in these epithelial cells.

Such a nephritis is regularly secondary to other diseases, and does not give constitutional symptoms.

3. One in which the principal share in the morbid process is taken by the stroma, and in which the evidences of inflammation are permanent connective tissue in the stroma, with, in addition, the lesions of exudative nephritis.

Such a nephritis is regularly a permanent and progressive lesion, and is attended with well-marked constitutional symptoms.

REMARKS ON THE ALBUMINURIA OF PREGNANCY.[1]

By FORDYCE BARKER, M.D., LL.D.,

NEW YORK.

The general pathology of acute Bright's disease has been so ably discussed by previous speakers that it is my purpose to confine my remarks closely to the subject which you assigned to me, and to restrict them to the limit of time which you suggested. What I have to offer will therefore be condensed in the fewest words. If the aphoristic style, which I must adopt, may seem to some presumptuously dogmatic, I hope that it will be excused on the ground that the time and occasion demand that ideas should be expressed in the fewest words.

I prefer to use the term "albuminuria of pregnancy," as defining the topic which I am to discuss, rather than that of acute Bright's disease, for the following reasons:

1. Bright's disease has become so familiar to the public, as one which sooner or later must terminate fatally, that it inevitably depresses a patient, and especially carries terror to the minds of women during gestation, and to their friends. While the disease which we are discussing, if properly treated, results in recovery of a large majority of patients, why, then, should we deprive our patients of the positive benefit of confidence and hope by the use of a term which may be scientifically incorrect, inasmuch as the pathological conditions now accepted as belonging to acute Bright's disease may be, and sometimes are, absent in those cases where albumen is abundant in the urine, and where other general symptoms which, in the aggregate, we call albuminuria, may be found in an alarming degree?

2. I express my conviction, based on my experience and observation, that in nine cases out of ten, in private practice, where albuminuria is found in pregnant and parturient women, the structural lesions of the kidney, which can be properly designated as Bright's disease, did not exist previous to pregnancy; and even in hospital practice, where the organic changes exist in a larger proportion of cases, it is my belief, after a careful review of my experience, that the assertion I have just made is true in seven out of ten patients.

3. I may here express my conviction that the albuminuria of pregnancy and the organic disease which can be properly termed acute Bright's disease in the non-pregnant should be regarded, clinically, etiologically, and sometimes pathologically, as distinct diseases, requiring differing therapeutic treatment, and having essentially a different prognosis. They are allied diseases in the fact that both have many of the most striking phenomena in common, as albumen in the urine, and dangerous neurotic, gastric, and vascular disturbances of a similar character, and both may induce that peculiar form of blood-disease, with all its dangerous consequences, which we call uræmia.

I beg to say, here, that the terms albuminuria, uræmia, and Bright's disease are not synonymous or identical. Either condition may exist alone, but they are often associated, as cause or consequence of one or both of the other conditions. The symptoms of the disease we call albuminuria may exist for some time before albumen can be found in the urine—such as œdema, first in the lower extremities, gradually becoming general and invading the face; puffiness of the eyelids is generally present. The œdema sometimes extends to all the areolar tissues, and even dangerously fills the serous cavities.

Arterial tension, as demonstrated by small, hard, thready pulse, is a symptom of great importance. The patient often has a chlorotic or anæmic appearance; and if nausea, or vomiting, or other gastric disturbances come on in the later months of pregnancy, these symptoms should excite suspicion. The cerebral symptoms are very important, such as headache, dimness of vision, impaired hearing, and an unusual mental dulness, with unusual excitability. A marked decrease in the amount of the renal excretion is a very serious and significant symptom.

There have been various theories as to the causes of albuminuria in pregnancy: First, it may be entirely due to certain modifications of the system, resulting from pregnancy, as changes in the quality of the blood. During the period of gestation the blood becomes superalbuminous, as has been demonstrated by Claude, Bernard, and many others. There is increased demand for albumen for the nutrition of the fœtus. There are changes in the capillaries, which should be reserved for plastic alimentation. The urine of the fœtus normally contains albumen, but does not contain urea. Therefore the maternal albumen, which passes through the fœtus without being employed in its development, returns to the maternal system loaded with waste material. Robin asserts that in pregnant women hæmatosis is incomplete, and thus predisposes to an hydræmic state of the blood and relaxation of the tissues which facilitate the passage of albumen into the urine, which is notably increased by the arterial tension always found in this condition. Thus we often find serous plethora in pregnant women. Formerly I believed more fully than now in the mechanical theory, first suggested, I think, by Dr. Cormac, that in a large proportion of cases of albuminuria in pregnancy, especially in primiparæ, it was a result of venous congestion, caused by the pressure of the gravid uterus on the emulgent veins of the kidney. This may be one of the causes, but it is probably rare, as the pressure is very slowly developed, and the circulation adjusts itself to the changed conditions, as we are constantly seeing clinically.

This mechanical theory may be the explanation of a fact often observed, that in some patients, where repeated examinations have failed to detect albumen in the urine, it has been found abundantly after the process of parturition, especially if convulsions have occurred. The violent muscular contractions seem to have interrupted the venous circulation to such an extent as to produce acute hyperæmia of the kidneys, and afterward the urine is loaded with albumen. But the limit of time assigned to me does not permit of more prolonged discussion of these points, and I will only add that while our knowledge has been greatly advanced by recent investigators, among whom I should particularly mention Mahomed, Bouchard, Capron, Moricke, Gubler, Peter Rosenstern, and many others whose names at the moment do not occur to me, still I think we will all agree that renal pathology, in relation to its associations with pregnancy, is in a transitional state, with bright hopes as to our exact knowledge in the future. I leave all discussion of the pathology and treatment of the most serious of all the explosions which often occur in connection with the albuminuria of pregnancy to the gentleman who is to follow, Professor Charles Jewett.

---

[1] Made at the annual meeting of the Medical Society of the State of New York, Wednesday, February 8, 1888.

As every one must see, who examines the programme of this meeting, the great object of our President and his associates has been to make the papers and discussions of practical value. I hope our late President may not feel that I am encroaching on his domain, if I add a few words on the treatment of puerperal albuminuria, expressing the convictions of a long experience in the briefest terms consistent with clearness. I will not detain the Society by a discussion of such treatment as is now accepted by all well informed physicians, but will only refer to those plans of treatment in regard to which there is a difference of opinion among physicians of equal ability and experience.

In the treatment of the albuminuria of pregnancy the most prominent indications are, obviously, to restore the normal condition of the blood, and to prevent the tendency to, or overcome existing, renal congestion. Of course, the means to secure these objects must vary extremely, according to the special conditions of each case. Thus, in one, anæmia, hydræmia, and general feebleness of the vital powers predominate. In another, plethora and abnormal activity of the digestive and assimilative functions; and a strong tendency to renal and cerebral congestion is a prominent characteristic.

The question of diet is one of the most important points. The first class need a nutritious diet, avoiding the danger of overtaxing the kidneys by restricting the amount of nitrogeneous food, and chalybeates may be required. I have often seen great benefit from giving the patients, for weeks before parturition, a teaspoonful of glycerine, 3 parts, and tincture of chloride of iron, 1 part, in a wine-glass of water, after each meal. In a few cases wine, or some other form of alcohol, is often beneficial.

In the other class of cases an exclusive milk-diet, so strongly urged by Tarnier, is, I think, very important. It would be a waste of time for me to discuss details of treatment familiar to all, such as the importance of saline purgatives to secure large serous intestinal discharges. The utility of diuretics in these cases is, I think, very questionable, except the indirect diuretic which results from the cardiac tonics, such as digitalis and the tincture of the chloride of iron.

If the albuminuria is attended with symptoms indicating a threatening of uræmia, or it already exists, then more active treatment is necessary.

Venesection I regard as of the first importance, even if the patient be hydræmic, as it relieves from the effect of serous plethora. The bleeding removes tension from the brain, relieves congestion of the lungs, sets the breathing free, removes pressure from the laboring heart, and eases the congested kidney of the load that embarrasses it.

In medical journals I now and then read the report of a case of albuminuria successfully treated by the use of pilocarpine. When the therapeutic effects of jaborandi or its alkaloid, pilocarpine, were first made known to the profession, it was received with great enthusiasm, as a remedy which would probably prove of great service in the treatment of albuminuria.

In the Transactions of this Society for the year 1879 will be found a paper, which I had the honor to read, on this subject. I will only say that my convictions are still the same as expressed in that paper—that the remedy is in this class of cases unsafe and uncertain, and that we have other resources much more safe and reliable.

The necessity and propriety of inducing premature labor in the albuminuria of pregnancy is one not yet settled. It was first advocated by Braun, of Vienna, some thirty years since. Some years later, Tarnier, of Paris, became the most prominent advocate of this measure, but he has very essentially modified his views in late years. Some ten years ago it was strongly advised by several of our most prominent obstetrical teachers and writers in New York, under conditions which seemed to me quite unjustifiable, and I then published a protest, which some present may have seen.

It was assumed that albumen in the urine, persistent for some time in large proportions, and if attended with extensive serous infiltration of the general areolar tissue, demanded the induction of premature labor to prevent eclampsia. I think the doctrine accepted by the vast majority of the present day is, that albuminuria. even in its greatest development, never justifies this procedure, unless accompanied with unquestioned evidence of perilous uræmia, and other resources for the cure of both the albuminuria and the uræmia have been exhausted.

The theory of this practice is based on the great danger of eclampsia; but this danger is much less than has been assumed, for while about 1 in 25 pregnant women have albuminuria, convulsions occur in only 1 out of 485 or 500 cases. Then it must be remembered that considerably more than half of the cases of convulsions come on during labor, whether spontaneous or induced, and more than one-quarter after parturition. I think the evidence is conclusive that, by appropriate prophylactic treatment, the albuminuria and the uræmia may be almost absolutely averted. It is many years since I have seen a case of eclampsia in a patient who has had this prophylactic treatment. I will take this opportunity to speak of one agent which, I think, may prove of great value in the treatment of the uræmia of pregnancy, but which, so far as I have seen, has never been mentioned in this connection—and that is nitro-glycerine, in doses of from $\frac{1}{100}$ to $\frac{1}{50}$ of a minim, repeated every three or four hours. Its effect is to speedily reduce arterial tension and allay spasm of the cerebral and renal arterioles, and thus indirectly increase the functional activity of the kidney and marvellously quiet the nerve-storm so characteristic in these patients. [Two cases, illustrative of these effects, were then briefly related.]

The existence of amblyopia and amaurosis has been urged by some as a reason for the induction of premature labor.

This reason has been chiefly brought forward by some of our prominent ophthalmologists, and in THE MEDICAL RECORD of January 28, 1887, is a very interesting article on this subject.

This subject has been fully discussed by me, in a work on the puerperal diseases, published in 1874, which, I suppose, it is hardly to be expected that even the most prominent ophthalmologists should be familiar with. I will not detain the Society by again going over this ground. I will conclude with this formula of my view on this point: The premature induction of labor may be justifiable and absolutely a duty, when the symptoms of albuminuria and uræmia have resisted previous medical treatment, and are of so grave and dangerous a character as to threaten the life of mother or child.

SULPHUR IN CHLOROSIS.—Acting on theoretical considerations, Schulz and Strübing have given sulphur in chlorosis. From six cases thus treated they draw the following conclusions: 1. In cases of simple chlorosis in which iron has no effect, the general condition is markedly improved by sulphur. 2. After sulphur has been given for some time, treatment with iron could be started and continued successfully. 3. Sulphur is not well borne in cases of chlorosis complicated with catarrhal, inflammatory conditions of the digestive tract. The following is their formula: ℞. Sulph. depur., 150 grains; sacch. lact., 300 grains. M. Ft. pulv. Half a teaspoonful three times daily.—*Medical Chronicle.*

SULPHO-BENZOATE OF SODA IN THE DRESSING OF WOUNDS.—At a meeting of the Academy of Sciences of Paris, Dr. Heckle read a note on the results obtained by the employment of the sulpho-benzoate of soda in the dressing of wounds. These results have been so satisfactory that the author considers this agent as being far superior to all the antiseptics now in vogue, without having any of the inconveniences inherent to them.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 11, 1888.

COMMITMENT OF THE INSANE.

THE successful effort of a sane lady to secure admittance to an asylum for the insane, in this city, through the ordinary method of procedure, has given a renewed interest to the question of the security of the community against improper commitment to asylums under our present laws. The undertaking was undoubtedly a very clever piece of journalistic enterprise, and was very cleverly executed. The result has been, as we anticipated, a crop of measures before the Legislature, to amend the lunacy laws, especially in relation to the procedure of commitment of the insane.

Before discussing the bill now in hand, it may be well to state that the law of commitment of the insane in this State is nearly a transcript of the English law, which has been regarded as a model. It requires that the person shall first be personally examined by two physicians of reputable character, graduates of an incorporated medical college, and who have been at least three years in the actual practice of their profession, such qualifications having been certified to by a judge of a court of record. These physicians fill out blank forms of certificates, stating their reasons for believing the person insane, and before a notary or judge make oath to the correctness of their certificates. These certificates are then presented to a judge of a court of record, who may approve the finding of the physicians, or he may take additional testimony, or he may summon a jury and have a full trial. On the approval of the certificates by the judge the papers are complete, and the person may, within ten days, be confined in an asylum. The procedure is certainly very simple, and proceeds on the principle that the insane are sick people, and require hospital care; that they should be disturbed as little as possible, and that friends are generally very sensitive about giving publicity to the nature of their affections. That the law has worked well in England there is no question, and it has yet to be proved that any harm has befallen an individual during the sixteen years that it has been in operation in this State.

The bill before us, which is now in the committee of the Legislature, proceeds upon an altogether different principle. An insane person is regarded as a criminal, and he is spoken of as the "accused." It provides that a judge of a court of record must issue "a mandate directing the sheriff to summon, within five days, at the county court-house, not less than twenty-four persons qualified to serve as jurors in the courts of records in said county, from whom twelve persons shall be chosen, in manner as petit jurors are chosen for trial of criminal actions, to serve as a jury to try the question of insanity of the accused." The "accused" must have at least five days' notice of the trial, "and such trial shall be conducted, in all respects, as a trial for felony." The "accused" is entitled to be present at the trial, to be defended by counsel, to be accorded reasonable opportunity to prepare for trial, to call witnesses, to challenge jurors, and "to exercise every other right and privilege which is accorded by the constitution and laws of this State to a person indicted for a felony." The trial is to be conducted in behalf of the people, and the district-attorney, or counsel directed by the judge for that purpose, must manage the prosecution. The judge shall also see that the "accused" is provided with good and efficient counsel. If the jury shall find the "accused" to be insane to such degree as to render it unsafe for him to be at large, they shall so specify in their verdict, etc. The remaining provisions of the bill are of similar import.

To one who is familiar with the progress which this State has made, during the century of its existence, in ameliorating the condition of the insane, and in making public provision for their better care and treatment, such a bill as this is a singular anachronism, the more remarkable because it is reported to emanate from a society for the protection of the insane. The old adage, that history repeats itself, is curiously illustrated by the introduction of this bill into the present Legislature. Just one hundred years ago—viz., in 1788—a measure was introduced into the Legislature of this State, the spirit and the essential features of which were the same as this bill. It stands on the statute-book as the first effort in the first Legislature of the State of New York to provide for the insane. It is entitled "An Act for apprehending and punishing disorderly persons," and is an exact transcript from the vagrant laws of England. The following is the original act:

"*Whereas*, There are sometimes persons who, by lunacy or otherwise, are furiously mad, or are so far disordered in their senses that they may be dangerous to be permitted to go abroad; therefore, be it enacted that it shall and may be lawful for any two or more justices of the peace to cause to be apprehended and kept safely locked up in some secure place, and, if such justices shall find it necessary, to be there chained, if the last place of legal settlement be in such city, or in any town within such county."

The law passed by the Legislature of 1788, like the bill before the Legislature, placed the insane in the category of vagrants and criminals, and proceeded against them as persons accused of crime.

It must be presumed that the advocates of this bill are really inspired by humane motives, and believe that they are providing measures by which the sane cannot be committed as insane. But the practical results of such legislation would be that no better safeguards would be provided against the commitment of the sane, while untold hardships would be inflicted upon the insane. It is a matter of history that the verdicts of juries in cases of alleged insanity are reliable only in proportion to the competency of the medical witnesses in each case. Hence the opinions of juries, in themselves, are unimportant, but the competency of medical examiners is all-important. While it is probable that our methods of procedure in commitment might be made more definite and reliable, it is certain that the method proposed in this bill would be a retrograde step of the most serious character.

PYROMANIA.

The extraordinary and unfortunate case of incendiarism in the Hospital for Ruptured and Crippled, in this city, has naturally excited no little interest and comment. For several weeks a series of attempts, one of which was successful, to set fire to the building were made. At last it was discovered that the author of the mischief was a girl of about eleven. She confessed her crime and expressed some sorrow, but was unable to tell why she acted as she had done. According to reports, she was an intelligent and attractive child, and had shown no signs at any time of entertaining malice, or of having criminal propensities. Her mother was reported to be insane.

The case seems to be one of instinctive juvenile mania of Morel. Clinically it belongs to the form of monomanias known as pyromania. This peculiar disorder is known to affect the young more especially, and more often the female than the male sex. It is classified by Emminghaus ("Die psychischen Störungen im Kindesalter") among the anomalies of instinctive feelings. By French writers it would be classed among the monomanias of the degenerate.

Emminghaus states that the fascination for fire, *Sucht nach Feuer*, is peculiar to many children. If of healthy organization, they soon learn its dangers; but if there is defective volitional power, it leads the victims to accidents and even crimes.

Dr. More, in an article upon incendiary monomania, calls attention to the fact that it often occurs among young persons, and cites a case of Henke's: A girl of fourteen, who suffered from nostalgia, twice set fire to the house in which she lived. She said that she was continually possessed with a desire to burn the house, and she had the delusion that a ghost was urging her on to do it.

Livi, cited by Hammond, claims that while incendiarism may be often committed under the influence of delusions, it may also be the result of a morbid instinctive impulse. It is a fact that pyromania is extremely uncommon as an isolated symptom. There are, as a rule, other signs of insanity present.

EXTRA-PERITONEAL INCISIONS IN THE LINEA ALBA FOR PURPOSES OF EXPLORATION.

At the Second Congress of Russian Physicians, Professor Sneguireff, of Moscow, advocated extra-peritoneal incision of the abdominal walls, in various directions, for purposes of examination. Whenever necessary, these incisions were to be supplemented by the performance of ordinary laparotomy.

Not long afterward Bardenheuer, independently, as it would appear, of the Russian surgeon, also described and advocated this method of arriving at an exact diagnosis in otherwise doubtful cases of abdominal disease. According to the recommendations of these surgeons, the incisions should be made laterally in various directions.

In a recent issue of the *Centralblatt für Chirurgie*, Dr. A. v. Gubaroff takes up this subject, but advises the incision to be practised in the median line. The anatomical reasons for this preference he gives as follows: The peritoneum is easily detached at the median line, as well as for a distance of over one inch to either side of it; the elasticity of this membrane is so great that almost the entire abdominal cavity can be explored by palpation in this way. The best results are obtained by employing bimanual palpation, one hand being placed in the incision-wound, and the other in various regions of the abdomen.

The author asserts that by this means the anterior surface of the pancreas, the pylorus, the duodenum, the kidneys and ureters, a large part of the under-surface of the liver, including the gall-bladder, and, in fine, almost every organ contained in the abdominal cavity may be felt. The author agrees with Sneguireff and Bardenheuer in asserting that these incisions and manipulations are quite devoid of danger, and that this method of procedure should constitute the first step of an exploratory laparotomy in the ordinary sense.

It may be well to remember in this connection that Bardenheuer's suggestions have not yet received the sanction of the leading surgeons either in his own country or elsewhere, probably for the excellent reason that the method may not be quite as free from danger as it is claimed, and further, because the average operator of to-day has no hesitation in opening the abdomen for purposes of diagnosis as well as treatment. It seems to us, however, that if extra-peritoneal incision is to be given a trial, the median line is the proper site for its performance.

Death by Electricity.—The full report of the commission appointed to investigate the most humane and practical method of carrying into effect the death-sentence has reached us. It, in a measure, confirms the view expressed by us, that exact experimentation, in order to determine the best practical mode of applying electricity so as to cause death, is wanting. Two experiments are cited, in which dogs were used, and a wire, or iron bit, placed in the mouth for one of the connections. Death was instantaneous, and the action of the heart was at once and permanently stopped. It does not follow from this, or the results of the electrical dog-killing apparatus at Buffalo, that a man, seated in a chair, with a head and foot rest forming the electrodes, would be instantly killed, unless, at least, the head and feet were firmly bound to wet sponges. This seems a somewhat brutal proceeding, and it might seem extremely so with a struggling man or woman. The *Medical Press* says, *à propos* of this subject: "The present condition of electrical science, however, does not inspire confidence. We can put up with an occasional 'wobble' in the electric light, or an occasional delay or error in the despatch of a telegram, but there must be no 'wobbling' when life has to be disposed of."

News of the Week.

An American Physician before a Berlin Society.—Dr. Frank Donaldson, Jr., of Baltimore, recently read a paper, by request, before the Physiological Society of Berlin, "On the Method of Isolating the Mammalian Heart for Experimental Research."

The Virginia State Board of Medical Examiners.—The law regulating by a rigid examination the practice of medicine in Virginia, is said to be in danger of being repealed. According to the *Alexandria Gazette* (January 21st), two bills have been introduced into the Virginia Legislature, one to repeal the law providing the State Board of Medical Examiners, and the other to exempt from passing before this Board graduates of all State medical schools.

We have Itinerant Doctors in this country, but they are, without exception, pestilent quacks. In Roumania, however, doctors are scarce, and an itinerant dispensary has been established, which perambulated through the country last summer and treated nine thousand patients.

Medical Expert Witnesses.—An English judge is said to have laid down from the bench, as recently as the year 1882, the following classification of liars: 1, liars; 2, great liars; 3, scientific witnesses. Apropos of this piece of sagacity, we notice in the *Medical and Surgical Reporter* a reference to a suit for damages on trial in New York. The medical expert for the plaintiff testified that the woman, who had, previous to the accident, been unusually strong and hardy, suffered from concussion of the spine, and that it was only a question of time when she would die of her injuries. The expert for the defence testified that the woman had no disease, that her spine was in its normal condition, and that the only trouble was hysteria. Inasmuch as she fell forward, he held it was impossible for concussion of the spine to occur.—*Medical Age.*

A Spanish Gynecological Congress.—In the month of April next a congress will be held at Madrid under the auspices of the Spanish Gynecological Society. It will comprise three sections—obstetric, gynecological, and one for diseases of children.

A New Anæsthetic: Erythrophlœine.—Dr. Lewin, of Berlin, has examined an arrow-poison called haya, a poison sent to him by Messrs. Christy & Co., and received by them from Africa. The following particulars are gleaned from an article published in the *British and Colonial Druggist.* The poison was found to contain some pieces of sassy-bark, the ordeal poison of the Africans (*Erythrophlœum judiciale*). Dr. Lewin separated an alkaloidal substance, soluble in water, and not reducing Fehling's solution. Having often heard of an arrow-poison which caused insensibility, Dr. Lewin proceeded to ascertain whether the haya-poison could produce anæsthesia of the cornea, and he found that it could, though it was a little longer in developing than from cocaine; it lasted, however, for eight or ten hours, as it gradually faded. The application produced a passing irritation of the conjunctiva. Dr. Lewin suspected that the anæsthetic property came from the *erythrophlœum.* He obtained a two per cent. solution of the hydrochlorate of erythrophlœine, and found that it produced anæsthesia of the cornea, but with considerable irritation. Weaker solutions were non-irritating, but required ten to fifteen minutes for their effect.

The Best Drink is Tea, according to M. Germain Sée. Tea-drinking is increasing in France, the amount consumed having doubled in the last thirty years. Americans are not tea-drinkers, but consume coffee largely. In England the use of tea is being condemned.

A Laryngological Society has been organized in England, and it has already about fifty members, including most of the prominent laryngologists of Great Britain and Ireland.

Abandonment of Homœopathy.—Professor Samuel O. L. Potter, of San Francisco, gives, in *The Lancet,* the following as his reasons for abandoning homœopathy. He says: "I abandoned homœopathy before entering into practice, because my observation of the reception by homœopaths of Dr. C. Wesselhoeft's reproving of carbo-vegetabilis, and Dr. Sherman's work in the "Milwaukee Test" of 1879, proved to me that no crucial drug-experimentation, conducted under scientific safeguards, could meet with any degree of appreciation from the majority of that sect. I was further impressed by finding that ninety-nine out of every hundred so-called homœopathic physicians were in the habit of resorting to regular therapeutics whenever there was any active therapy to be done."

The New York County Medical Society.—In the final report of the County Medical Society's Treasurer, Dr. O. B. Douglas, an interesting table is given, showing that the total receipts of the Society, from the date of its foundation to the year 1879, were $18,838.38. From 1879 to 1886–87, the receipts were $25,517.12. The total membership of the Society is now 974, of whom 605 have paid their dues, and 369 are in arrears.

The Bill for the Improvement of the Condition of the Assistant Surgeons of the Navy has been reported upon favorably by the sub-committee of the Senate Naval Committee, and it is the understanding that it will be so reported to the Senate by the full committee.

A Pension Fund for Nurses and Hospital Officials.—The sum of $100,000 has been subscribed as the beginning of a fund for pensioning nurses and hospital officials in Great Britain. There are, it is said, about twenty-five thousand persons of these classes in that country. The idea of pensioning nurses, etc., is probably a good one. But in this country the pension idea has not a great hold, except so far as soldiers in the late war are concerned. We understand that the feature of the English pension fund is to be, in a measure, that of a mutual provident insurance company. All persons who wish to share the benefits of the fund subscribe a sum of about thirty dollars, and pay certain annual dues. The success of the project is due largely to the energy of Mr. Henry C. Burdett. An association of nurses already exists, so that British nurses seem likely to be well provided for.

Warts Rapidly Disappear under the internal administration of arsenic, according to Dr. B. G. Pullin, in the *Bristol Medico-Chirurgical Review*.

Dr. William E. Vermilye died at Flushing, N. Y., February 2d, aged sixty years. He was a graduate of the University Medical College, and practised for some years in this city.

The Legal Status of Private Hospitals.—A very important decision, if correctly reported, has been recently made by a California court. It is that a private hospital in a populous neighborhood is a nuisance and must be removed.

Marine Hospital Service.—A bill has been introduced into the United States Senate, providing that medical officers of the Marine Hospital Service of the United States shall hereafter be appointed by the President, by and with the advice and consent of the Senate; and no person shall be so appointed until after passing a satisfactory examination in the several branches of medicine, surgery, and hygiene before a board of medical officers of the said service. Said examination shall be conducted according to rules prepared by the Supervising Surgeon-General, and approved by the Secretary of the Treasury and the President.

Hepatic Stimulants.—Dr. George Bird, of London, has recently called attention to the value of calomel, in doses of a tenth of a grain, as a hepatic stimulant, and I have frequently employed it, in the form of the triturates, for the purpose. I believe you obtain from these small doses, given every three or four hours, as good an effect as from a single dose of five or even ten grains, and that without inconvenience to the patient. Podophyllin resin, in doses of a quarter of a grain every four hours, is equally useful.—*Dr. Wm. Murrell.*

Ginger-drinking is said to be greatly on the increase, especially among women. Ginger extracts are used, and the stuff is taken chiefly on account of its alcohol, although some have claimed that ginger itself causes a distinct form of inebriety. The sale of ginger in Maine was at one time so great that it was declared by the courts to be an intoxicant, and placed among the alcoholic drinks prohibited.

National Control of our Maritime Quarantine.—The Committee of the College of Physicians of Philadelphia, appointed to investigate the efficiency of our quarantine arrangements for the exclusion of cholera and other epidemic diseases, reported, some months ago, the very inefficient condition of our maritime quarantine. In a later address the matter is presented at greater length, and the arguments for a national control of quarantine are fully and cogently presented. To secure the passage of a law to this effect the Committee invite the co-operation of the medical profession as a body, and as individuals, to assist in influencing legislation by the following means: "1. The passage of formal resolutions recognizing the necessity of national control of maritime quarantine, and urgently recommending the matter upon the consideration of your representative in Congress. 2. Strenuous efforts to enlist popular sentiment in support of such legislation. 3. The enlistment of the influence of the local medical and public press."

Reports of Societies.

MEDICAL SOCIETY OF THE STATE OF NEW YORK.

Eighty-second Annual Meeting, held in Albany, February 7, 8, and 9, 1888.

Tuesday, February 7th—First Day—Morning Session.

The Society convened in the court-room in the City Hall, and was called to order at 9.25 o'clock by the President, Dr. Alfred L. Loomis, of New York.

Prayer was offered by Rev. A. V. V. Raymond.

The President delivered his inaugural address, having appointed the following committees:

Committee on Credentials—Dr. James D. Spencer, Dr. O. B. Douglass, Dr. Wm. B. Brown.

Committee on Business—Dr. Frederick A. Castle, New York; Dr. John W. Whitbeck, Rochester; Dr. A. Walter Suiter, Herkimer.

THE PRESIDENT'S INAUGURAL ADDRESS.

The President maintained that each member had a right to present his own views and experience, and to criticise those of others, and even apparently insignificant facts might be worthy of record. But in addition to its scientific work, this Society must attend to the welfare of the profession as a whole, and to that of every member of it. Up to 1880 there was

NO LEGAL PROVISION AGAINST QUACKERY;

but now, by the efforts of the Society, a law had been passed under which the New York County Society had prosecuted eighty-five individuals, and had had sixty-five convicted and punished by fines and imprisonment. The President recommended that other county societies follow this example.

In 1885 the Society had recommended a bill for a

BOARD OF MEDICAL EXAMINERS,

and a bill had been suggested which was a compromise with some who opposed the views of the Society. The President had made particular personal efforts for this bill, and it was almost passed. Now the time is favorable for passing this bill, or some similar measure, and the President recommended further effort in that direction.

Lawyers very often fail to treat

MEDICAL EXPERTS,

giving evidence in trials in a sympathetic spirit, and it would tend to greatly improve the status of medical expert testimony if some arrangement could be made by which the medical experts would have the right to ask questions for themselves. The President recommended that some attempt should be made to alter the law accordingly.

THE TREATMENT OF THE INSANE

is a very important subject, which needs investigation and improvement in this State, especially in regard to the county asylums, and the President recommended that the Society take up the subject.

AN ENLARGEMENT OF THE SOCIETY

had been urged by many, but it was felt by the President that it was not advisable to alter the organization of the Society.

This Society should have some voice in the

REVISION OF THE UNITED STATES PHARMACOPŒIA,

and it would be well to appoint a committee for that object.

After alluding to the prominent members of the Society who had died during the preceding year, he would suggest that the President be empowered to appoint a committee to prepare

OBITUARIES OF DECEASED MEMBERS,

which should be inserted in the "Transactions" of each year.

Dr. William C. Wey, of Elmira, Dr. Willis E. Ford, of Utica, and Dr. Daniel Lewis, of New York, were appointed a committee to consider and report upon the President's inaugural address.

Dr. William C. Wey moved that the by-laws be suspended and all names of candidates for permanent membership be referred to the Committee on Nominations. Seconded and carried. The following were made members by invitation: Dr. William Pepper, of Philadelphia; Dr. Francis Bacon, of New Haven (President Connecticut State Society); Dr. Edward R. Campbell, of Bellows Falls (President Vermont State Society); Dr. John W. Ward, Trenton (President New Jersey State Society); Dr. A. P. Grinnell, Burlington, Vt.; Dr. H. P. Walcott (Massachusetts State Board of Health); D. J. C. Irish, Lowell, Mass. (Delegate Massachusetts State Society); Dr. C. C. Bartholomew and Dr. W. S. Dailey, of Ogdensburg, N. Y.; Dr. Joseph O'Dwyer, New York City; Dr. John H. Jewett, Canandaigua; Dr. Daniel S. Burr, Binghamton; also Dr. J. D. Bryant, Dr. W. M. Polk, Dr. J. H. Girdner, Dr. W. M. Thomson, Dr. C. C. Lee, Dr. W. H. Draper, Dr. L. A. Stimson, Dr. R. F. Weir, Dr. B. F. Curtis, and Dr. F. H. Bosworth, of New York City; Dr. E. F. Brush, of Mount Vernon; and Dr. Roswell Park, of Buffalo.

Dr. William C. Wey, of Elmira, reported for the Committee on By-laws, that the

BY-LAWS OF THE WESTCHESTER COUNTY SOCIETY

had been investigated by them, and found in accordance with the laws of this Society, and that they recommend the admission of that County Society to the State Society. It was moved and carried that the report and recommendation of the Committee be adopted.

The Committee on Legislation reported, by Dr. Laurence Johnson, that the bill for

THE REGISTRATION OF MEDICAL PRACTITIONERS

had become a law, the full text of which is given in the "Transactions" of the Society for 1887. W. A. Purrington, Esq., was employed as counsel for the Society to forward the passage of this bill, and the Committee presented a request for the payment of legal expenses. The report was adopted, and it was voted that the expenses be paid as requested.

The Society was then divided by the President into a Medical and a Surgical Section.

SURGICAL SECTION.

Dr. A. M. Phelps, of New York, President of the Section, in the chair.

The Section was called to order at 10.10 o'clock.

Dr. Henry G. Piffard, of New York, read a paper entitled

NOTE ON THE TREATMENT OF LUPUS.

Years ago the speaker had urged energetic measures for the treatment of lupus—excisions, curetting, and cauterization. But in some cases this is impossible, and milder means must be employed; yet green soap, carbolic acid, bichloride of mercury, and other agents had not been satisfactory. For the last ten months he had employed local applications of

HYDRONAPHTHOL

in a ten per cent. solution in liquid gutta percha, or in a twenty per cent. rubber plaster. He had treated six cases with these means—and one case had not relapsed; the others had relapsed, as they will under any method. The solution was applied daily for a week, when a crust formed. The plaster was applied and allowed to remain on for one week. The applications had to be made three or four times. The pain was slight. Dr. Piffard considered the method of treatment superior to any other for such cases.

Dr. P. A. Morrow read a paper on the

TREATMENT OF LUPUS,

advocating treatment by scarification. Treatment of this disease should be early and energetic, but it must avoid disfigurement (especially in the usual situation of lupus—upon the face), and leave a smooth, superficial, movable, and non-contractile cicatrix. Chemical cauterization causes disfiguring cicatrices. Galvano-cautery, applied by the linear or the punctate method, is better. Curetting is not good, and excision makes a disfiguring scar. The best method of treatment is that by linear scarification, which acts by dividing the small vessels. Pain is generally not great—if it should be, local anæsthesia by freezing or the use of cocaine may be used.

Dr. T. Fox, of New York, said that for extensive patches all methods of treatment which necessitate ulceration must be avoided on account of the disfiguration which followed. For very small nodules fine dental instruments are very good as curettes. For extensive patches he knew of nothing so good as the local application of hydronaphthol in rubber plaster, or, still better, in an ointment with sulpholeate of soda, which does not repel water.

Dr. Piffard could not agree with Dr. Morrow in regard to excision, which he considered the best method for small patches—just as it is for epithelioma. Nor did he like the actual cautery, except to be used after a thorough curetting, and even then the solid pencil of nitrate of silver was as good. Some cases do not respond to any treatment whatever.

Dr. Sherwell, of Kings County, has found pyrogallol an excellent local application.

Dr. Morrow had not tried hydronaphthol, but thought no agent had a selective action upon lupus.

A paper by Dr. O. D. Pomeroy, on

SOME POINTS IN THE DIFFERENTIAL DIAGNOSIS OF DISEASES OF THE EAR BY THE USE OF THE TUNING-FORK,

was read by title.

Dr. Hermann Knapp then read a paper on the

EXTRACTION OF CATARACT WITHOUT IRIDECTOMY,

with a report of one hundred successive cases. The speaker said that the revival of the classical flap-operation for the extraction of cataract would be hopeless without the assistance of cocaine, eserine, and the antiseptic method. These prevented the two great drawbacks of the old method—prolapse of the iris and suppuration, which had destroyed innumerable eyes. The combination of

IRIDECTOMY WITH EXTRACTION OF CATARACT

by Graefe had reduced the loss of eyes by one-half. After describing the method of operation in the new operation, Dr. Knapp stated that in the present series of

ONE HUNDRED SIMPLE EXTRACTIONS

prolapse of the iris had occurred in 11 cases; all, with one exception, regained good sight. Suppuration occurred in one case, the only failure of the series. It was produced by secondary infection in a patient suffering from cystitis and diabetes. The visual results in this series had been good beyond precedent, for ninety-five per cent. of the patients regained good vision (nineteen per cent. had V. = $\frac{20}{20}$); four per cent. moderately good; one operation failed. Dr. Knapp felt sure that the high rate of visual acuteness was largely due to the subsequent discission of the capsule—an operation free from danger, which he performed in the majority of the cases.

Dr. David Webster, of New York, then reported a case of

FATAL MENINGITIS CONSECUTIVE TO OPERATION FOR EXTRACTION OF CATARACT

caused by panophthalmitis. The operation was done with the assistance of cocaine, and without accident. On the second day the patient showed symptoms of dementia, tearing off his dressings. On the fourth day chemosis set in, and on the eighth day panophthalmitis was well marked. There were symptoms of meningitis upon the twelfth day, and the patient died a week later. So far as the reporter knew, this was a unique case.

Dr. D. B. St. John Roosa, of New York, said that no one had done more than the author of the paper on extraction of cataract to advance the technique of that operation. He felt, however, that each case had a particular method suitable to it, and careful selection should be made. Yet the method without iridectomy was his favorite also, and he had himself invented a modification of that operation. He had, however, been content with a vision of V. = $\frac{20}{40}$, and was unwilling to increase the danger of an operation in an attempt to improve on that. Heredity he considered an important factor in the etiology of the disease ; in one family he knew of seven cases, in another of four. As to antisepsis, he considered it unnecessary—only cleanliness.

Dr. Knapp had never known of such a case as the one of meningitis just reported. He thought the method introduced by the last speaker excellent for some cases, but no one method suited all.

Dr. Webster liked the simple extraction for suitable cases, and in a series of 12 cases had had prolapse of the iris in only one—in which he had not employed eserine.

Dr. J. H. Glass, of Utica, had seen panophthalmitis follow in two cases of simple extraction of cataract followed by a secondary iridectomy. He considered antisepsis very essential.

Dr. Fessenden N. Otis, of New York, then gave a demonstration of

NEW URETHRAL AND BLADDER INSTRUMENTS,

including an electric endoscope and an improved aspirator for litholapaxy. He stated that in Bigelow's aspirator the sieve became so clogged with débris and blood as to be useless, as was shown by a photograph taken of one after an operation. He desired to state that he had lately examined two cases, sixteen and thirteen years after he had performed internal urethrotomy, and found not the least relapse.

A paper by Dr. S. Wight, of Brooklyn, on

A CASE OF FORWARD DISLOCATION OF THE ULNA,

was read by title in the absence of the author.

Dr. W. B. De Garmo, of New York, read a paper upon the

RESULTS OF MECHANICAL TREATMENT OF HERNIA,

founded upon the observation of 1,000 cases. Eighteen were irreducible, and yet in 7 of these recovery was obtained. It is true that hernia does not recur as frequently as has been supposed after mechanical treatment, or after operation for radical cure, for the statistics of the latter deal only with unusually severe cases, but the rate of mortality after these operations is still so much higher than that of the operation for strangulation, that it does not seem justifiable. About twenty-five per cent. recovered under mechanical treatment so as to go without a truss, as shown by examination after six months.

Dr. F. H. Potter, of Buffalo, read a paper upon

GALVANO-PUNCTURE FOR ENLARGED TONSILS,

in which a sharp-pointed electrode was plunged into the tonsil twice, at frequent sittings. The method avoided the dangers of hemorrhage, and was not painful.

Dr. Sherwell, of Kings, had never met a case of hemorrhage after tonsillotomy, and thought there was some danger of it after this method of galvano-puncture.

Dr. Lewis S. Pilcher, of Brooklyn, had independently hit upon the same method and had found it very useful, especially in timid patients, the circuit not being closed until the instrument was in the mouth.

Dr. Clarence C. Rice, of New York, had found the method tedious, although useful in some cases in adults. In children hemorrhage is not found after tonsillotomy, and he preferred that operation. For adults he preferred the galvano-caustic snare.

The Section then adjourned.

MEDICAL SECTION.

Dr. Alfred L. Loomis, the President, called the Section to order.

Dr. H. Kretzschmar, of Brooklyn, read a paper upon the

USE OF ALCOHOL IN CERTAIN FORMS OF FEVER.

Alcohol was in certain cases a most important means of preserving life. It did not stand between food and medicine, but combined the properties of both. The amount to be given, and the frequency of administration must be carefully and exactly prescribed. It was the prince of antiseptics, and the best remedy we possess in diphtheria, dissolving the membrane, reducing the temperature, and calming the pulse.

Dr. Frederick A. Castle, of New York, put each dose of the stimulant in a separate small bottle to avoid evaporation.

Dr. J. Leonard Corning, of New York, read a paper on some

NEURO-THERAPEUTIC MEMORANDA,

in which he described a method of applying medicaments directly to the spinal cord, in certain tetanic and painful conditions, by the hypodermic syringe. He had employed strychnine in this way. The speaker also described the benefit he had derived from the prolonged use of faradism in paralysis of the face due to rheumatism.

Dr. Willis E. Ford, of Utica, read a paper on

REFLEX NERVOUS DISTURBANCES,

describing some cases treated both by removal of the exciting peripheral cause, and by constitutional measures. Thus, chorea, epilepsy, and masturbation were found to be caused by diseased ovaries and tubes, phimosis, and urethral caruncle ; and although the removal of the cause failed to cure, the addition of bromides was followed by recovery.

Dr. E. D. Fisher thought in all chronic cases it was necessary to treat the central lesion produced by the long continuance of the irritation, as well as to remove the cause of irritation itself.

Dr. J. L. Corning thought that many ovaries had been removed for so-called reflex irritation, where the trouble was really a central lesion.

Dr. Andrew F. Currier, of New York, read a paper on

THE INFLUENCE OF OBESITY IN YOUNG WOMEN UPON THE MENSTRUAL AND REPRODUCTIVE FUNCTIONS.

He found the law that, when obesity occurred in multipara reproduction ceased, as a mark of the exhausted forces of the system. In unmarried women it marked only a diversion of the vital forces, and was curable. In the latter cases it was accompanied by pain, and constipation was generally present. The causes were hereditary disposition, luxurious habits, over-indulgence in starchy and fatty foods ; and the treatment was addressed to the correction of these.

Dr. Francke H. Bosworth, of New York, read a paper on the

ACTION OF CAUSTIC APPLICATIONS ON THE NASAL MUCOUS MEMBRANE.

Chemical agents did not differ from the actual cautery. He preferred chromic acid, and with this agent pinned the mucous membrane at exactly the desired points.

Dr. Edward F. Brush, of Mt. Vernon, read a paper on

BOVINE TUBERCULOSIS.

He commenced by remarking that after all discussion respecting tubercle, we are confronted with the questions: "Is bacillary tuberculosis conveyed to the human race from animals affected with this disease?" He pointed out that, of all domesticated animals, the bovines were the most subject to tuberculosis; that, indeed, the human and the bovine races were pre-eminently tubercular.

The percentage of cattle infected with tuberculosis in England is placed at five per cent., and increases till, in some of the thorough-bred Jersey herds of the Northern States, Professor R. A. McLean declares that twenty per cent. are so affected.

The reason why more human beings are not infected is, that the normal temperature in the human race is so much lower than in the bovine, that the germ will not grow till the temperature is raised in the former to the degree naturally existing in the latter, namely, 101° to 103° F.

The same rule holds, also, in localized tubercular deposits, where the temperature is raised by reason of injury to a degree permitting the growth of the bacillus. The cultivation of tuberculosis in other animals confirms this view, as the resistance to tuberculosis decreases in proportion as the natural temperature of the animal increases. Thus, in the dog, with the lowest temperature, resistance is good; while in the common fowl, with the highest temperature, resistance is *nil.*

The Section then adjourned.

First Day—Afternoon Session.

The President, Dr. A. L. Loomis, in the Chair.

A COMMITTEE ON NOMINATIONS

was appointed by The President, consisting of Dr. Henry G. Piffard, New York, for the Society; Dr. A. M. Phelps, New York, for the First District; Dr. L. H. Miller, Brewster, Second District; Dr. A. Vanderveer, Albany, Third District; Dr. C. W. Hamlin, Middleville, Fourth District; Dr. George Seymour, Utica, Fifth District; Dr. W. C. Wey, Elmira, Sixth District; Dr. J. L. Heffron, Syracuse, Seventh District; Dr. J. O. Roe, Rochester, Eighth District.

Dr. Clarence C. Rice, of New York, read a paper on the

REMOVAL OF LARYNGEAL GROWTHS

with O'Dwyer's snare, in conjunction with intubation of the larynx, in the case of a child in intense dyspnœa, the intubation having been done first to save its life. The tube was removed and the growths extirpated with the snare—a wire loop with a cutting edge on the interior.

ACUTE BRIGHT'S DISEASE.

Dr. Francis Delafield, of New York, opened the discussion with a paper upon its

PATHOLOGY AND CLINICAL HISTORY (see p. 151).

Dr. A. Jacobi, of New York, followed with a paper upon

ACUTE BRIGHT'S DISEASE IN CHILDREN.

The speaker stated that many cases run an insidious course, the temperature being low, and appearing lower than it is, for the incipient œdema lowers the surface temperature, and even the temperature taken in the axilla by the thermometer is deceptive. Œdema and dyspnœa are the first marked symptoms—œdema of the pericardium, lungs, glottis, and brain. Increase of blood-pressure causes cerebral symptoms and cardiac trouble. Diarrhœa is also found. Sometimes the symptoms appear very suddenly—such as a sudden loss of sight. The urine contains albumen; although this is occasionally absent, and then the urine is scanty, of low specific gravity, containing very little urea. Casts and epithelia are found.

One of the causes of acute nephritis in the adult is wanting in children, for the arteries are not degenerated. The most frequent cause is the poison circulating in the blood in the

ACUTE INFECTIOUS DISEASES,

especially frequent in scarlatina and diphtheria, but very rare in typhoid fever, probably because its course is not so acute and the range of temperature during it being lower. Rheumatism is for the same reason also less frequently a cause, even when endocarditis is present. The speaker had seen it follow purpura, renal hemorrhage being one of the symptoms, and it also complicates croupous pneumonia, and even catarrhal pneumonia and bronchitis. Irritant drugs cause it, and especially chlorate of potash.

EXPOSURE TO COLD

is a very frequent cause, and in these cases suppression of urine is a common symptom, or hæmaturia, or hæmoglobinuria, which may return with every fresh exposure. As to the

PROGNOSIS

in typhoid fever, it is sometimes bad, even fatal, but generally the patient recovers entirely. In scarlatina, chronic nephritis may result, or uræmia may set in early and cause death. In diphtheria, on account of the difference in the poison, the lower range of temperature, and the weak heart, render hæmaturia not so common. In some cases of diphtheria copious albuminuria may even be followed by improvement in the general condition.

Dr. D. B. St. John Roosa read a paper on

THE PATHOLOGICAL CHANGES IN THE EYE IN ACUTE BRIGHT'S DISEASE,

stating that nothing new of importance had been discovered in this branch of the subject, and the ophthalmoscope revealed nothing, the case being very different from the clinically similar sudden loss of vision from poisoning by drugs. Cases of amaurosis from nephritis generally recover. The action of the pupil remains normal in some cases—probably because the nerve-centres are not affected beyond the corpora quadrigemina.

Dr. Richard Van Santvoord, of New York, followed with a paper upon the

CARDIAC CHANGES IN BRIGHT'S DISEASE.

Dr Van Santvoord stated that it had always been recognized that there was a causal connection between the condition of the heart and nephritis. Dilatation of the heart, or hypertrophy accompanied by dilatation, is sometimes caused by scarlatinal nephritis, the changes being made evident by the pulse and the development of a murmur; but autopsy generally shows very little alteration in the tissues.

Dr. Fordyce Barker, of New York, discussed

ACUTE BRIGHT'S DISEASE IN THE PUERPERAL STATE (see page 155).

Dr. William S. Ely, of Rochester, discussed the

TREATMENT OF BRIGHT'S DISEASE,

saying that there is no specific. The kidneys must be given rest, transferring their functions to the bowels and the skin. Every case must be treated according to its individual indications.

Dr. Eugene Beach, of Gloversville, and **Dr. Joseph Peso**, also joined in the discussion.

Dr. Delafield then closed the discussion.

Dr. J. O'Dwyer then exhibited some new instruments and some pathological specimens showing the results of

INTUBATION OF THE LARYNX.

Intubation has been done on adults for erysipelas of the larynx, to aid in the removal of a tracheotomy tube, for syphilis and tuberculosis, for diphtheria, and for stricture. When a tracheal fistula exists, the latter must be sealed, because the secretions dry so readily upon the cannula.

Dr. Hale read a paper on the

RESULTS OF INTUBATION

in a series of several cases, in one of which the removal of the cannula was very difficult.

First Day—Evening Session.

The President, Dr. A. L. Loomis, in the Chair.

Dr. A. Vanderveer, of Albany, read a paper upon the

HISTORY OF ABDOMINAL SURGERY IN ALBANY,

with a summary of seventy five cases of laparotomy performed for a great variety of conditions.

DISCUSSION ON SALPINGITIS.

Dr. William Goodell, of Philadelphia, and **Dr. Paul F. Mundé**, of New York, who were to have taken part in the discussion of the pathology and symptoms, sent word that they would be unable to be present.

Dr. Charles Carroll Lee, of New York, discussed the

ETIOLOGY,

stating that inflammation of the tubes was similar to that of the uterus, for both developed from the same tissues, the ducts of Müller. The etiology was not well understood, because it was impossible to make a diagnosis until very late in the disease, as the early stages were apt to run their course without symptoms. It is generally secondary to endometritis, and of two forms, catarrhal and parenchymatous. Exposure to cold and repressed menstruation were the usual causes in the primary form.

Dr. George Seymour, of Utica, discussed the

PROGNOSIS.

The tendency is toward recovery in the majority of the cases, but the sequelæ are often serious, and sometimes even fatal. Many cases can be cured without operation.

Dr. Frederick A. Castle, of New York, discussed the

MEDICAL TREATMENT.

The speaker said that generally the disease was not recognized until it was beyond the reach of treatment. The gonorrhœal variety was the least amenable to treatment. Absence of sexual excitement, saline purgatives, enemata of hot water, and arterial sedatives were indicated. Massage had been advised, but was dangerous, for pus might be thus carried into the peritoneal cavity.

Dr. William M. Polk, of New York, then discussed the

SURGICAL TREATMENT.

He said that in pyo-, hæmato-, or hydrosalpinx the only treatment was removal, as also in tuberculosis. In parenchymatous salpingitis the walls were so thickened that the tube was practically destroyed, and as we do not know whether this will end in resolution, we must also remove them. When only one tube is diseased we must remove both tubes, unless we can prove that there is no endometritis, otherwise inflammation will be sure to develop there also.

SHOULD THE TUBES BE REMOVED FOR CATARRHAL INFLAMMATION?

The speaker thought not, for absolute recovery is possible. When there are adhesions in these cases which cause symptoms, it will be well to perform laparotomy and break them up—a much safer proceeding than attempting to do so by massage.

Dr. W. Gill Wylie, of New York, discussed

THE RESULTS OF OPERATIVE TREATMENT,

giving some results from his own work, and concluding that operative interference was not very dangerous.

Dr. A. Vanderveer, of Albany, closed the discussion, saying that removal, and removal close to the uterus, was the only method of treatment. Care must be taken not to promise immediate results from operation.

Dr. C. C. Lee, of New York, read a paper on

ALEXANDER'S OPERATION IN COMPLETE PROCIDENTIA OF THE WOMB,

stating that, out of a score of times in which he had performed the operation, he had done it three times for procidentia. Contrary to the belief of many, he had found the operation curative.

Dr. W. Potter, of Buffalo, then read a paper upon the

TREATMENT OF PELVIC INFLAMMATIONS, AND THE MANAGEMENT OF THEIR RESIDUES

by local applications, tampons, and removal of pus.

Dr. William M. Polk, of New York, read a paper on

VAGINAL HYSTERECTOMY,

with a report of eight cases. The mortality of this operation is about twenty-five per cent., and is much better than that if only the cases of the best operators are included. The results as to recurrence are satisfactory and improving. Of the eight cases, two died from the operation, and two had recurrence within a year.

The Society then adjourned.

Wednesday, February 8th—Second Day—Morning Session.

The President, Dr. A. L. Loomis, in the Chair.

The Society was called to order at 9.30 o'clock, when prayer was offered by the **Rev. Walter D. Nicholas**.

The minutes of the preceding meeting were read and accepted.

The following names were added to the list of invited guests: Dr. C. M. Lefler, Gloversville; Drs. W. C. Marselius, S. R. Morrow, F. M. Trego, Robert Babcock, W. G. McDonald, R. D. Craig, Albany; Dr. J. H. Girdner, New York.

The Treasurer, **Dr. Charles H. Porter**, of Albany, then read his report, which was adopted on motion.

Dr. Porter then reported on the Merritt H. Cash Prize Fund.

Dr. William C. Wey, of Elmira, reported on behalf of the Committee on By-Laws, that they advised the adoption of the President's suggestion, not to admit as delegates the representatives of unchartered medical societies. The report was adopted.

Dr. Wey then reported for the Committee on the President's Address, recommending that the bill in regard to a State board of medical examiners be referred to the Committee on Legislation, with instructions to urge its adoption upon the Assembly. The suggestions as to expert testimony to be referred to the same committee, with instructions to report. The questions of the treatment of the insane and national quarantine to be referred to special committees to report at this meeting. That the recommendation not to admit delegates of voluntary unchartered medical societies as members of this Society be approved. That a committee be appointed to consider the revision of the United States Pharmacopœia, and report in 1890. Finally, that a committee be appointed to prepare biographical notices of deceased members for the Transactions.

The report was adopted.

The Secretary, Dr. W. Manlius Smith, read a communication from the Philadelphia Medical Society, concerning national quarantine—already considered; and from the Georgia Medical Society, urging action to secure the removal of customs duties on drugs and surgical instruments. Referred to Committee on Legislation.

Dr. D. B. St. John Roosa moved that the New York Polyclinic and the New York Post-Graduate Medical School be authorized to send one delegate each to this Society, subject to the regulations with regard to delegates from medical colleges. The resolution was adopted.

Letters were then read by Dr. J. W. Whitbeck, of Rochester, for the Business Committee, from the presidents of several State medical societies, regretting their inability to be present.

The President then asked the Society to decide whether it would remain in one body or divide into sections.

Dr. Roosa moved that there should be no division. Carried.

Dr. William H. Thomson, of New York, then read a paper on the distinction between

FUNCTIONAL AND ORGANIC DISEASE OF THE NERVOUS SYSTEM.

The speaker said that probably we shall never find any lesions for true functional disorders, any more than for a fit of anger. These disorders are marked by total intermissions, which are never found in true organic disease, although the latter may have great remissions. Functional diseases are always peripheral, never central, although the centres may be affected secondarily. Before organic changes in the central organs take place, the latter may be rendered unusually unstable. Treatment should accordingly be directed to removing the peripheral irritation.

Dr. D. B. St. John Roosa, of New York, referred to a case of paralysis of the third cranial nerve, which was entirely intermittent for two years, and then became permanent, the cause being supposed to be a tumor pressing on the nerves, first only in congestion, and then by its growth. Was not this an organic disease?

Dr. Thomson replied that in the intermittent stage of the symptoms the tumor was, in fact, only a peripheral irritant, and there was no true organic lesion until the constant pressure produced the permanent changes.

Dr. A. H. Smith, of New York, inquired why ipecac could produce asthma in some persons if that was really a peripheral disease.

Dr. Thomson replied that that was the point he wished to emphasize—that such idiosyncrasies were due to personal peculiarities of the peripheral nerves, and not to the central organs.

Dr. William H. Draper, of New York, read a paper on the

DIETETIC TREATMENT OF THE GOUTY DIATHESIS,

in which he stated that gout was usually considered due to over-indulgence in nitrogenous food and alcohol. But it is found in herbivora also, and later investigations show that for out-of-door muscular exertion the best diet is one composed of carbo-hydrates, while sedentary brain-workers require a nutritious albuminous diet. Gouty persons have an incapacity to digest carbo-hydrates. The treatment suggested was limitation of starch and sugar in the diet, exclusion of wine and beer (if necessary to give alcohol, dilute spirits are to be prescribed), exclusion of fruits, and increase of exercise out of doors.

Dr. Francis Bacon, of New Haven, President of the Connecticut State Society, was introduced.

Dr. E. V. Stoddard, of Rochester, read a report from the Committee on Hygiene, recommending certain alterations in the organization of the local boards of health necessary to increase their efficiency; legislation to prevent the sale of nursing-bottles with long tubes, and of canned vegetables colored with salts of copper. The report was accepted on motion.

Dr. Joseph D. Bryant, of New York, read a paper on the treatment of

PENETRATING GUNSHOT WOUNDS OF THE CRANIUM.

Hemorrhage should be stopped, depressed fragments of bone and all foreign bodies removed, and the wounds thoroughly drained. Statistics show that of sixty-six cases in which the bullet was removed the mortality was forty per cent., while in one hundred and seventy cases it was fifty-seven per cent. Of the recoveries when the bullet was removed the recovery was complete in forty-one per cent., while when the bullet was not removed it was complete in only twenty per cent.

THE BALL SHOULD BE REMOVED

immediately when its situation could be found, but no operation should be made to search for a bullet in an unknown situation. A large, light, rigid probe must be used, and passed without force, best in such a way that the force of gravity will make it enter the bullet-wound. The ball is to be removed by a counter-opening when it lies against the opposite side of the skull, and such an opening will admit of search for and removal of the ball if it has been deflected, and also for

THROUGH DRAINAGE.

Dr. Bryant described an original method for locating the distal end of a probe passed through a bullet-wound, and recommended the telephonic probe very highly. Horsehair drainage is excellent for wounds entirely penetrating the cranium, and sometimes irrigation.

Dr. John H. Girdner, of New York, then gave a demonstration of the

INDUCTION BALANCE AND TELEPHONIC PROBE

—the former for locating a ball without contact with it, the latter for recognizing it when touched.

Dr. A. Ross Mathewson, of Brooklyn, then read a paper on a case of recovery after an

EXTENSIVE COMPOUND FRACTURE OF THE SKULL,

with considerable loss of brain-substance and complicating fungus cerebri. The fracture occurred in a lad whose head was crushed by a horse's hoof stepping upon it. The patient was shown to the Society.

Dr. Henry Flood, of Elmira, read a paper on

DEPRESSED FRACTURES OF THE SKULL,

stating that in many experiments upon the cadaver he had failed in producing a depression of the external table without depression of the internal table.

Dr. Glass, of Utica, related a case in which a ball had been located but not removed, and in which there were no marked symptoms, and asked if an operation was indicated.

Dr. Bryant replied that in such a case the ball should be allowed to remain, unless symptoms or the induction balance gave evidence that the ball had begun to change its position, when it should be removed.

Dr. Charles Stover, of Amsterdam, then read a paper on the interdependence of

LOCAL, STATE, AND NATIONAL HEALTH BOARDS,

with a plea for their unification. Statistics showed that health boards diminished the death-rate; but combined action was absolutely necessary for success.

The President appointed a Committee on the Care of the Insane, consisting of Dr. A. Jacobi, New York; Dr. W. E. Ford, Utica, and Dr. C. R. Agnew, New York. Also a Committee on National Quarantine, of Dr. Daniel Lewis, New York; Dr. Charles Stover, Amsterdam, Dr. E. V. Stoddard, Rochester. Also a Committee on the Revision of the Pharmacopœia, of Dr. F. A. Castle, New York; Dr. Laurence Johnson, New York, and Dr. E. V. Stoddard, Rochester.

Dr. O. J. Welsey, Broome County; Dr. W. B. La Moure, Albany; Dr. L. Balch, Albany; Dr. W. Rider, Rochester; Dr. L. H. Hills, Broome County, and Dr. E. Sill, Jefferson County, were made invited guests.

The session then closed.

Second Day—Afternoon Session.

The President, Dr. A. L. Loomis, in the Chair.

The meeting was called to order at 2.40 o'clock.

Dr. A. S. Hickey, of Auburn, read a paper upon a case of

PERSISTENT VOMITING OF PREGNANCY

with melancholia, successfully treated by continued rectal alimentation.

Dr. R. Jeffery, of Brooklyn, presented a portable storage battery.

Dr. A. Walter Suiter, of Herkimer, read a paper on the

DISPOSAL OF DEAD BODIES,

warning against embalming by an undertaker, which might conceal the evidence of a crime.

Dr. W. Manlius Smith, of Syracuse, moved that the question presented in this paper be referred to the Committee on Legislation. Carried.

Dr. William C. Wey moved that members who had served for two years previous to the passage of the new by-law be eligible to election as permanent members. Adopted.

DISCUSSION ON INTESTINAL OBSTRUCTION.

Dr. Lewis A. Stimson, of New York, read a paper upon the

PATHOLOGY AND SYMPTOMS.

After enumerating the various causes of acute intestinal obstruction, the speaker pointed out the symptoms which accompanied each. In fifty per cent. of the cases of subacute and acute intussusception, a tumor can be felt in the abdomen; the less acute the case, the more difficult the diagnosis. Even in stricture there may be no previous symptoms, as in one case of stricture in the colon, so close that an appleseed was caught and obstructed it, with the result of death in a few hours.

STERCORACEOUS VOMITING

was not always a sign that the matter came from the large intestine, for the contents of the ileum acquire a fæcal odor. All cases may be divided into those in which nothing but operation can give relief, and those in which relief may be spontaneous. Almost the only cases of the latter class are intussusception and stricture of the large intestine, both of which have peculiar symptoms, and are not impossible of diagnosis.

Dr. R. F. Weir, of New York, remarked that surgery could save something over thirty per cent. of these cases. Could any of the physicians give us an idea of how many cases recovered under medical treatment?

Dr. L. A. Stimson moved that the President appoint a committee to collect and investigate as many cases as possible of recovery without operation which were known to members of the Society. The motion was carried.

Dr. William C. Wey, of Elmira, discussed the question,

HOW LONG SHALL THESE CASES BE TREATED MEDICALLY?

Desperate cases do recover, said the speaker, and in confirmation he briefly related two cases in his own practice, with fæcal vomiting and commencing collapse. He would say that if symptoms do not improve very soon, an operation is indicated. In one case in which he had operated he found a band, but gangrene had already occurred and collapse was present, and the case terminated fatally.

Dr. Simmons, of Utica, had seen two desperate cases recover without operation, in one of which preparations had been made to operate.

Dr. Albert Vanderveer, of Albany, discussed the question,

WHEN SHOULD OPERATIVE MEASURES BE RESORTED TO?

The speaker said that he was very anxious to know what to do in such cases as the following: A man, twenty years of age, had an acute attack of colic, supposed to be due to lead, which was not relieved by drugs, and ended in death in seventy-two hours. Early operation was necessary. Only this morning he had operated in a case in which he feared that the operation was too late—a man, thirty-three years of age, last movement of bowels five days ago, vomited green materials two days ago, sudden aggravation of symptoms yesterday; operation, stricture of gut found, probably cancerous, resected. The specimen was shown.

Dr. Arpad Gerster, of New York, remarked that the only way to gain knowledge upon this subject, and to be able to make an early diagnosis, was to carefully observe every case of ordinary colic, even in its early stages. Palpation thus made will often discover a tumor in the abdomen. Tympanites soon develops, and then operation is difficult or impossible. Many cases will always remain obscure.

Dr. R. F. Weir remarked that no time should be lost in endeavoring to ascertain the exact cause of the obstruction, for this

REFINEMENT OF DIAGNOSIS

will generally be impossible. The important point is to determine whether or not obstruction really exists. Among all the cases subjected to operation, the existence of some cause, irremediable in any other way, has been almost invariably discovered; so that every successive operation renders the surgeon less afraid of operating unnecessarily. It is time that some of this confidence should also be imparted to the physician. In regard to spinach-green vomited material, he would say that it is not to be assumed as a proof of the existence of peritonitis—and there was no peritonitis in Dr. Vanderveer's case. As to the

PROPER TIME FOR OPERATION,

he felt, for the present, inclined to say that, if obstinate constipation, pain, and vomiting had existed for forty-eight hours, laparotomy should be performed at once.

Dr. W. Gill Wylie, of New York, had lately seen two cases of perityphlitis with very latent symptoms, and thought that in every abdominal disease it was necessary to operate very early, before symptoms were marked.

Dr. I. N. Goff, of Cazenovia, was anxious to learn some means of making a reliable early diagnosis, for in the country it was no small matter to bring a surgeon a long distance to a case in vain. He had seen a case of recovery from intussusception by sloughing, in an adult.

Dr. William S. Ely, of Rochester, remarked that, according to Dr. Weir's remarks, peritonitis was in every case a surgical, as distinguished from a medical disease.

Dr. Weir replied that such was the fact—traumatic peritonitis being very rare.

Dr. Roswell Park, of Buffalo, then discussed the

CHOICE OF OPERATIONS.

The speaker remarked that the presence of a tumor in the abdomen was said to indicate the necessity for laparotomy; but, in one such case, he had opened the abdomen and found a malignant growth in the pelvis—an artificial anus was made, and gave temporary relief. Authorities differ upon the choice of operations—thus, Treves, Kümmell, Le Dentu, Terrier, and Trélat, favor laparotomy; while Madelung, Schede, Verneuil, Le Fort, and Rochet favor enterostomy. Rydygier holds that obstruction due to the pressure of a tumor, or to partial twisting of the gut, indicates enterostomy, and may be entirely relieved by it. Schede suggests enterostomy to relieve the urgent symptoms, and laparotomy performed soon after, to remove the obstruction, if it persists. In conclusion, the speaker said that

ENTEROSTOMY

was indicated whenever the diagnosis was uncertain, in cases of cancer of the gut, and whenever tympanites was very great; and

LAPAROTOMY

was indicated when the diagnosis of a curable cause was certain, when a small tumor could be felt in the abdomen, when a neoplasm was present which admitted of resection, and when peritonitis was present and required drainage of the peritoneum.

Dr. Robert F. Weir, of New York, discussed the question

HOW SHOULD THE OPERATION BE CONDUCTED?

Dr. B. Farquhar Curtis, of New York, then read a paper on the

RESULTS OBTAINED BY OPERATIVE INTERFERENCE,

which will appear in a future issue.

Dr. Abraham Jacobi, of New York, remarked that the medical profession had the tendency to divide itself into specialties—one body writing prescriptions, another wielding the knife only. He had long been known as an advocate of the right and duty of every medical practitioner to

PERFORM ALL LIFE-SAVING OPERATIONS,

such as tracheotomy and herniotomy, and he would now advocate the performance of laparotomy for acute intestinal obstruction by any practitioner out of reach of a surgeon by specialty. He only advised early operation and antiseptic methods. The diagnosis of

INTUSSUSCEPTION

was not difficult, and operation ought to be possible in the earliest stages. In fecal impaction there was usually a colitis and peritonitis, and some septic absorption, and in these cases the thermometer, *placed in the rectum*, would show a

SLIGHT RISE OF TEMPERATURE,

which was absent in other forms of obstruction during the first three or four days, and he considered this a useful point in diagnosis. He would strongly warn against puncture of the gut for the relief of tympanites, as the openings did not close afterward on account of the paralysis of the gut due to over-distention, and peritonitis would certainly follow.

Dr. Francis Bacon, of New Haven, would also urge the importance of

EARLY OPERATION.

The early operator was the man who would have the best results. He felt constrained to warn those without experience in surgery, and especially abdominal surgery, against rashly undertaking these cases. When watching Mr. Tait perform an oöphorectomy, one is inclined to think abdominal surgery an easy matter, but in these cases the elaborate description just given of the technique of the operation enabled one to form some faint idea of the complexity and

TREMENDOUS DIFFICULTIES

to be encountered in these operations. He favored a very large incision, which adds greatly to the ease of manipulation while not increasing the risk of the operation. But he must emphasize the chances for recovery without operation; he had recently seen three cases of intussusception, two of which were cured by inflation of the bowel.

Dr. J. Pero, of Oswego, related a case of intestinal obstruction.

Dr. R. B. Bontecou, of Troy, showed a patient upon whom he had performed a

SUCCESSFUL LAPAROTOMY FOR OBSTRUCTION,

a man about thirty years of age, who had had the symptoms of obstruction for one week, but was in fair condition when the operation was performed, immediately upon the appearance of fecal vomiting. A band was found near the ileo-cæcal valve, and removed. The incision had healed by first intention, and although it was only about a month since the operation, there appeared to be no weakness of the abdominal wall.

Dr. Topman, of Syracuse, related a case of acute intestinal obstruction, due to a mass of gooseberry seeds, relieved by enemata, in which a cast of the intestine, apparently a false membrane, was passed later.

Dr. Roswell Park then closed the discussion, remarking that he agreed with Dr. Weir in preferring chloroform to ether in these cases, but he found that thorough narcosis produced by morphine before the operation diminished the shock.

INFLATION OF THE BOWEL

in attempts to overcome the obstruction he considered a dangerous procedure, having seen a case so treated in which a perforation of the gut was found at the subsequent laparotomy, and resulting fatally. He had seen

SUFFOCATION BY REGURGITATED MATTER

result in one case in which a band had been successfully removed, when the operator put considerable pressure on the distended gut to reduce it within the abdomen, death taking place in a few minutes.

Dr. Arpad Gerster, of New York, read a paper on the

OPERATIVE TREATMENT OF JOINT-DISEASE.

He stated that every particle of diseased tissue must be removed in tuberculosis of the joints, just as in cancer, but that only the diseased tissues should be removed. Esmarch's bloodless method was of great service in these operations to prevent loss of blood, and systemic infection (by embolism, etc.) by the tuberculous matter. Long-continued after-treatment was necessary, but passive motion was injurious.

The session then closed.

Second Day—Evening Session.

The Society met in the Senate Chamber of the Capitol at 8.15 o'clock, with Dr. William C. Wey, of Elmira in the chair, to hear the annual address of the President, Dr. A. L. Loomis (see p. 141).

Dr. S. B. Ward, of Albany, moved a vote of thanks to the President for his address, which was carried.

The Society then adjourned.

A banquet was served at the Delavan House after the evening session.

THURSDAY, FEBRUARY 9TH—THIRD DAY—MORNING SESSION.

THE PRESIDENT IN THE CHAIR.

The Society was called to order at 11 o'clock, and prayer was offered by REV. JOSEPH LITTELL.

DR. A. WALTER SUITER, of Herkimer, moved, on behalf of the Committee on Business, that Dr. Bell be allowed to enlarge his Merritt H. Cash Prize Essay of last year. Adopted. Also that the papers read by invited guests at this meeting be referred to the Committee on Publication, for publication in the "Transactions."

DR. DANIEL LEWIS, of New York, read a paper on

CHIAN TURPENTINE IN THE TREATMENT OF CANCER.

DR. C. R. AGNEW, of New York, discussed Dr. Roe's paper.

DR. SAMUEL B. WARD moved to raise the salary of the Secretary. The motion was adopted.

OFFICERS ELECT.

DR. JOHN L. HEFFRON, of Syracuse, Secretary of the Committee on Nominations, read the following nominations by the Committee:

For *President:* Dr. Samuel B. Ward, Albany. *Vice-President:* Dr. A. Walter Suiter, Herkimer. *Treasurer:* Dr. Charles H. Porter, Albany. *Secretary:* Dr. W. Manlius Smith, Syracuse. *Censors:* Southern District—Dr. John S. Warren, New York; Dr. Walter B. Chase, Brooklyn; Dr. W. H. Helm, Sing Sing. Eastern District—Dr. Joseph Lewis, Albany; Dr. Thompson Burton, Fultonville; Dr. Leroy McClean, Troy. Middle District—Dr. Henry Flood, Elmira; Dr. Robert Frazier, Camden; Dr. I. N. Goff, Cazenovia. *For Syracuse University:* Dr. I. N. Goff, Cazenovia.

Committee of Arrangements: Dr. F. C. Curtis, Albany; Dr. Edward L. Partridge, New York; Dr. C. L. Merrill, Albany.

Committee on By-laws: Dr. George Seymour, Utica; Dr. F. F. Castle, New York; Dr. W. M. Smith, Syracuse.

Committee on Hygiene: Dr. E. N. Stoddard, Rochester; Dr. E. F. Brush, Westchester; Dr. J. P. Creveling, Auburn; Dr. Alfred C. Moyer, Syracuse; Dr. W. H. Bailey, Albany; Dr. W. C. Bailey, Albion; Dr. A. N. Bell, Brooklyn.

Committee on Legislation: Drs. Alexander Hadden; H. T. Pierce, New York; Dr. F. C. Curtis, Albany.

Committee on Ethics: Dr. A. Jacobi, New York; Dr. Arthur Matthewson, Brooklyn; Dr. H. R. Hopkins, Buffalo.

Committee on Prize Essays: Drs. George F. Shrady; Frank P. Foster, New York; Dr. Eugene Beach, Gloversville.

Committe on Publication: Dr. W. Manlius Smith, Syracuse; Dr. C. H. Porter, Albany; Drs. Daniel Lewis, O. B. Douglas, New York.

Honorary Members: Dr. Duane D. Simmons, Japan; Dr. Francis S. Shepherd, Montreal; Dr. B. F. Bear, Philadelphia; Dr. George E. Fenwick, Montreal; Dr. D. M. Wilcox, Lee, Mass.

Eligible to Honorary Membership: Sir Morell Mackenzie, London, England; Professor William Pepper, Philadelphia, Pa.; Dr. Max Schede, Hamburg; Dr. Reginald Harrison, Liverpool, England; Mr. Howard Marsh, London, England; Dr. Francis Bacon, New Haven, Ct.

Delegates to State and other Societies: Dr. A. Jacobi, New York; Dr. J. O. Roe, Rochester; Dr. B. F. Sherman, to Massachusetts. Dr. D. M. Totman, Syracuse; M. L. Bates, of Columbia; W. O. Moore, to Vermont; A. Jacobi, of New York, to Pennsylvania; Prince A. Morrow, to New Jersey; James McFie and George H. Rider, to Canadian Medical Association; George H. Fox, Clarence C. Rice, A. M. Phelps, of New York, to Ontario Medical Society; Henry G. Piffard, A. M. Phelps, of New York; M. L. Bates, of Columbia, to Connecticut; Frederick R. Sturgis, of New York, to Virginia; John O. Roe, of Rochester, to British Medical Association.

These gentlemen were duly elected.

VOTES OF THANKS.

DR. SAMUEL B. WARD, of Albany, moved a vote of thanks to the railroad companies, which had granted reduced fares. Adopted. Also a vote of thanks to the Mayor for the use of the Court-room of the City Hall for the meetings.

DR. JOHN O. ROE, of Rochester, read a paper on "The Frequent Dependence of Persistent and so-called Congestive Headaches upon Abnormal Conditions of the Nasal Passages."

PAPERS BY TITLE.

DR. A. W. SUITER announced the following papers read by title: "The Frequency of Preventable Blindness as shown in the State Institutions at Batavia," by Dr. W. Rider, of Rochester; "Cardiac Medication," by Dr. E. N. Stoddard, of Rochester; "Biographical Sketch of the Late Dr. Edwin Hutchinson, of Utica," by Dr. Thomas R. Pooley, of New York; "Idiosyncrasy," by Dr. A. R. Hopkins, of Buffalo; "Forward Dislocation of the Ulna," by Dr. J. S. Wight, of Brooklyn; "Biographical Sketch of Dr. W. M. Chamberlain," by Dr. John L. Warren, of New York; "Memoir of Dr. Wesley M. Carpenter, of New York," by Dr. Daniel Lewis, of New York; "Sketch of the Life of Dr. J. R. Boulware, of Albany," by Dr. C. H. Porter; "Treatment of Tubercular Affections of Joints," by Dr. A. M. Phelps, of New York; "Treatment of Tubercular Affections of Joints," by Dr. Virgil P. Gibney, of New York; "Biographical Sketch of Dr. B. A. Mynderz."

The Committee on Quarantine asked for more time, which was granted, with power to communicate with other societies.

DR. C. R. AGNEW, of New York, presented the report of the Committee on the Treatment of the Insane.

Discussed by Drs. Totman, Vanderveer, Blumer, and Brown, and adopted and referred to the Committee on Legislation.

THE PRESIDENT appointed a committee to prepare obituary notices of deceased members.

DR. DANIEL LEWIS moved a vote of thanks to the President for his labors in behalf of the Society. Carried.

The meeting then adjourned.

A NEW METHOD FOR IDENTIFYING BLOOD STAINS.—Dr. Ferry has described a new method for the medico-legal examination of blood stains. If the marks be upon linen, fibres are to be teased out with a needle and placed in a tube containing a one-thousandth solution of chloride of sodium. The fluid will soon become of a reddish-brown color. This liquid, then examined by the spectroscope, will present the characteristic lines of hæmoglobin. For the examination of the blood-globules one or two drops of a saturated solution of chloral are to be added to the fluid, when a rose-colored precipitate will be obtained. A drop of the precipitate is to be exposed on a thin plate over the flame of a spirit-lamp. A clear liquid will be separated, and may be taken up by blotting-paper. The pellicle of coagulum that is left should be colored with fuchsin, then washed with water. A drop of diluted acetic acid will render the preparation transparent, and the globules will become visible in bright red.—*Le Progrès Médical.*

AMPUTATION FOR GANGRENE IN DIABETES.—Professor König holds that in diabetic gangrene where, despite antidiabetic and local antiseptic treatment, the general and local symptoms do not improve, and further waiting involves danger to the patient, we should try to save life by a radical operation, such as an amputation, executed with the most scrupulous attention to antisepsis.—*Centralblatt für Chirurgie.*

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE QUEEN'S JUBILEE HOSPITAL—THE CONTROVERSY ON HOMŒOPATHY—THE DISCUSSION ON COW DISEASE —OBSTRUCTION OF THE BOWELS BY GALL-STONES, AND THE TREATMENT OF SUCH CASES—MR. HUTCHINSON'S HARVEIAN LECTURES ON LUPUS—A NATIONAL PENSION AND SICK FUND FOR NURSES.

London, January 24, 1888.

Law is proverbially uncertain, and both the litigants in the case of Millican vs. The Queen's Jubilee Hospital have found it so to their cost. The judgment obtained by Mr. Millican in his favor has been reversed on appeal, and he will have to pay the costs of the latter, both sides paying their own costs in the original action. Mr. Millican will perhaps emerge from the conflict but little lightened in pocket, as his friends have started a subscription to pay his expenses. The hospital, meanwhile, seems in direful need. From evidence given in another action, just brought against them by their printer, it appears that they have no funds, but are deeply in debt, and that all expenses are being met by the founder, Mr. Benham. This gentleman will probably hesitate ere he aspires to found another hospital. The experiment has in this case proved a costly one, as the institution owes him between two and three thousand pounds. The late Dr. W. Marsden, however, was the founder of two hospitals—the Cancer Hospital and the Royal Free Hospital—which have both survived and flourished.

The controversy on homœopathy aroused by the recent litigation has at last subsided. Nobody, I think, will be much the better for it. The homœopaths, however, are about to reprint the letters which have appeared in the *Times*, with a view of getting some additional publicity for them. Dr. J. C. Bucknill has written to disavow his identity with "J. C. B.," who is therefore now supposed to be Sir J. Crichton Browne, but the latter makes no sign. Dr. Brunton has penned a short letter in which he defends the orthodoxy of his book.

The discussion on cow disease, at the Pathological Society, was resumed on Tuesday last, and ended on the same evening. The conclusion is not satisfying, as nothing certain has been arrived at. Nevertheless, the free discussion of the subject which has taken place cannot but do good. The question of the identity or otherwise of the Hendon cow disease with that of the Wiltshire cows still remains an open one. As to the alleged causation of scarlet fever in man by disease communicated from the cow, no additional evidence in support of Mr. Power's views has been produced. Nor was any unanimity of opinion displayed as to whether the Wiltshire disease was really vaccinia, as Professor Crookshank believed it to be. The latter described at considerable length the minute anatomy and bacteriological features of the disease. Dr. Klein refused to regard Professor Crookshank's conclusions as final. The subject will doubtless be brought forward again at the Society in the near future.

At the last meeting of the Clinical Society a number of brief communications were made to the Society on the subject of obstruction of the bowels by gall-stones and the medical and surgical treatment of such cases. Dr. Maclagan read the notes of two cases which terminated fatally. In one, four stones, averaging an inch in diameter, were passed during life, and a fifth was found in the gall-bladder after death. There was a free opening between the gall-bladder and the duodenum. Mr. Clutton read a case in which he performed laparotomy for obstruction by a gall-stone in a woman aged seventy. The stone was felt in the lower end of the ileum, and was pushed through the ileo-cæcal valve. The patient made a good recovery. The president (Dr. Broadbent) referred to a fatal case of obstruction occurring in a woman ninety years of age. Dr. Ord related three cases. One proved fatal, and it was found, post-mortem, that the stone had ulcerated through the gall-duct. Dr. Gibbons related a case of biliary colic which subsided ten days before death. The latter was sudden, and due to perforation of the bowel by the gall-stone. Mr. Barker exhibited a calculus removed from the ileum after death. It measured four inches in circumference, and had caused complete obstruction. Mr. Heath suggested that systematic manipulation (under anæsthesia) might be valuable in such cases. Mr. Knowsley Thornton spoke with approval of Mr. Lawson Tait's plan of crushing the stone *in situ* with a pair of padded forceps, and thought it not very risky if the stone were first dislodged into a healthy portion of intestine. Mr. Gant narrated a case in which a concretion ulcerated through the vermiform appendix and caused fatal peritonitis. Dr. Glover referred to the value of olive-oil given freely internally. It facilitated the expulsion of the stones.

In his recent Harveian lectures, Mr. Hutchinson expounded his views on lupus at considerable length. The subject is one of those to which he has devoted great attention, and his utterances have therefore been awaited with considerable interest. He regards lupus as the head of a family, and not as a disease by itself. Its rarer forms were described at considerable length, and illustrated by numerous drawings and photographs exhibited. Mr. Hutchinson considers that there are bonds of essential relationship between ordinary lupus and lupus erythematosus, both clinically and pathologically. He thinks it probable that all forms of lupus are in occasional relationship with the tubercular and scrofulous diatheses, and also with cancer; but that, nevertheless, many patients with lupus appear in excellent health. He regards the disease as beginning in an inflammation under the influence of various exciting causes, and as deriving its peculiarities from the part affected.

A national pension and sick fund for nurses has been on the tapis for some time past. It was hoped by many that some portion of the women's jubilee offering to the queen would be devoted to this object. Such has not proved to be the case. Four city gentlemen thereupon came forward and subscribed between them the munificent sum of twenty thousand pounds. The fund, therefore, may claim to have made a good start, though not under royal auspices.

SURE CURES AND SPECIFICS.

To the Editor of The Medical Record.

Sir: Some of the "original" articles in the medical journals, on diphtheria, have an odor of self-praise or free advertising that offends the ethical sense and creates a distrust of their therapeutical value.

The "Memoranda" on the subject published in The Medical Record of the 24th ult., however, possess a seeming detail of circumstance and sincerity of statement that entitle them to respectful consideration.

He who believes he has a "cure" for ninety-seven per cent. or seven per cent. of "severe and unpromising diphtheria" should be both proud and pleased. A specific cure or antidote for the effects of a poison or harmful agent in a "severe" case should, by the ordinary processes of reasoning, be a cure for all other like or similar cases, barring accidents and the rare exceptions to all general rules. This being true, your contributor has furnished the profession what it has so long sought for in vain—a remedy or reasonably sure cure for diphtheria. Is the esteemed author of the "Memoranda" prepared to accept this conclusion? One day there is an equally encouraging account, in some medical journal, of the treatment of diphtheria by whiskey, brandy, or alcohol; the next brings a verified statement, in another publication, of hundreds of cases, "severe" ones, cured, with only three or four exceptions, by chlorinated lime. The advocates of these different, and frequently conflicting, theories of cure appear to believe absolutely in their respective methods, until unhappily their own, or the children of their immediate neighbors, begin to die of the affection with as little apparent effect from the operation of remedies as though there were not a physician in the whole town or city.

As your contributor remarks, "clinical evidence is the touchstone of the value of a remedy"—in a certain sense —and it is natural, though it is by no means true or logical, that a physician should regard a remedy useful in cases that recover under its administration. He admits that he has been misled in this respect in the past, and what guarantee has he that the next epidemic of diphtheria he has to encounter may not destroy his faith in "turpentine?" The history of the disease in this and other countries shows that the best physicians have only indulged in a misplaced confidence in this or that remedy, to have their faith destroyed by their own or the experience of equally intelligent observers. Turpentine may be a good germ-destroyer, but who knows that parasites cause diphtheria? and if they do, has it been proven that turpentine is a better parasiticide than is the blood itself?

The bichloride is recommended because it reduces the temperature. I have lately lost two patients with diphtheria whose temperature was subnormal from the commencement of the attacks. Patches of diphtheritic membrane were often found in the stool of these patients after the third or fourth day, and turpentine may have been indicated. It was given, though in smaller doses than those recommended by Dr. B——. A communication of this sort affords no proper opportunity to discuss the pathology or treatment of this disease. I merely wish to offer a mild protest against the general practice of publishing "cures" for so many of the human ailments, and especially to condemn the too frequent announcements that a remedy for this mortal malady has been found.

Many of the suggestions in the article under consideration, in my opinion, are wise and timely; but when we talk about "curing" so large a percentage of our cases, we are liable to embarrass, if not injure, our professional brethren; and the most ignorant quack, in or out of the profession, steps right forward with a "record" that not only equals but outstrips the statement of the "regular" physician.

Is it necessary, is it good policy even, for the medical profession to talk and write so much about "cures" when there are really so few of them? Does not this "state of things" do much, too much, toward keeping the profession on a level with quackery? It seems to me that nothing can more enhance and fortify the good name and respect which the medical profession should enjoy in the public estimation, than to tell the community the truth and educate the public to accept it as the best thing that can be done for the general welfare.

Respectfully,
S. B. H. Nichols, M.D.

Corning, N. Y., January 9, 1888.

LAWSON TAIT'S METHOD IN PLASTIC OPERATIONS.

To the Editor of The Medical Record.

Sir: I desire to ask for information regarding the peculiar operation for perineorrhaphy suggested by Lawson Tait. I saw it first described in Tait's work upon "Diseases of Women," New York, 1879. Coming from such a distinguished authority, I studied his directions for making the operation very carefully, but failed to comprehend them, until I saw the operation again described and illustrated in the "Transactions of the London Obstetrical Society," 1880, vol. xxi., p. 296. Since that date I have frequently practised it, and usually with success. I never take up a new work upon gynecology without at once looking for some mention of this operation, but with the exception of one English author, Arthur W. Edis, M.D., I have never seen it mentioned. I had some correspondence with Lawson Tait, in 1880, regarding the technique of the operation, and although I have never seen it practised by any other operator but myself, with one exception (Professor R. Ludlam, of Chicago), I have continued to practise it whenever I had an opportunity, until the present time.

The operation is especially adapted to lacerations of the perineum that involve the sphincter, and in cases where the rent in the rectum extends upward over half an inch. In those cases where the rent extends up an inch or more, the stitch of Dr. Emmet is uncertain as to the result, and in these cases the operation of Tait is, as a rule, usually followed by complete union. The principle of Tait's operation is: 1. No tissue is removed. 2. The edges of the rent are *split*, and the flaps are lifted up, and the mucous surfaces of same reverted, or turned back into the rectum, and go to their original position, while the vivified surfaces come together, and are carefully adjusted and co-adapted; and then sutures are introduced of sublimated Chinese silk, passing *between* the *two mucous surfaces* through their whole extent, so that, when tightened, the suture will not be seen or felt. The reverted flaps (mucous surfaces) are turned into the rectum where they belong, and actually form a sort of valve there, completely keeping out the fæces, and assist in the union of the raw surfaces. 3. In case healing and union should fail, the patient will be no worse than before the operation. In one case in the practice of the writer did this operation fail, and a second trial now upon the same patient seems to warrant the belief that a good result will follow.

In the operation I always use Bozeman's sharp pointed curved scissors, running the point of one blade through the skin and mucous membrane to such a depth as will allow me to turn the flap backward from each edge of the rent into the rectum. The vivified surfaces of these flaps must be accurately adapted to each other before the sutures are introduced. The sutures we formerly used were Pearsall's English silk, but now we use Chinese silk, previously kept in sublimate or carbolic acid. After the introduction of these sutures, the perineum may be closed. It would seem that the principle of Lawson Tait for making plastic operations might be formulated in a few words.

He does not, like other operators, commence by denuding the tissues and then removing the same, but he denudes by accurately *splitting* the *edges of any surfaces* where he wishes to join them, and turning what was the internal mucous membrane into the cavity of its viscus, and directly opposed to it will be the vivivied surfaces of the opposite corresponding flap, so that the mucous surfaces will be reverted into the rectum where they belong; or, if it should be a rent in the bladder, the edges, instead of being pared as in the old method, should be first split, and the mucous surfaces of same turned into the bladder where they belong, and the raw surfaces brought together, and stitches are then so introduced as to hold these raw surfaces together; all plastic operations are thus made by carrying out the above simple principles, whereby all tissue is saved.

It will be readily seen that this proceeding is especially adapted to operations for vesico-vaginal fistulæ.

Now, Mr. Editor, will you kindly inform me if this operation of Lawson Tait is approved of or employed by any gynecologist in your classic city? In case of perineal lacerations extending, say, an inch and a half up the rectum, it is my usual custom to unite the rectal rent by Lawson Tait's method, and, at a subsequent operation, close the perineum. The stitch employed by Tait is peculiar, and difficult to describe; it is really a buried stitch, introduced by a curved or straight needle across the rent, passed in the thickness of the septum *between* the *two mucous surfaces*, and when tightened can hardly be seen. Sometimes, for the rectal rent, one stitch only is necessary, but frequently a second may be required.

While recently attending a course of two months at one of the post-graduate medical colleges in your city, I never heard this operation mentioned, nor did I see it performed at the Woman's Hospital.

Any practical gynecologist will agree with me as to the uncertainty of the result in rupture of the perineum, where the rent extends more than half an inch into the rectum. Until I learned Lawson's Tait's method, I found that the operation, as taught by Emmet, sometimes failed.

It seems remarkable that in none of our recent works upon diseases of women notice should be made of the above surgical procedure.

T. Griswold Comstock, A.M., M.D.

507 N. Fourteenth Street, St. Louis, Mo.

HYPERTROPHY OF GLANDULAR TISSUE AT BASE OF TONGUE.

To the Editor of The Medical Record.

Sir: I have just seen in your issue of December 17th the interesting article of Dr. Gleitzmann on "Hypertrophy of the Glandular Tissue at the Base of the Tongue." Although the bibliography at the end of the paper refers to my recently published second edition of "The Throat and its Diseases," and also to my address at the Philadelphia County Medical Society, the author has overlooked my paper at the First International Congress of Laryngology, held at Milan in September, 1880, and published in the *Comptes Rendus* of the Congress.

I venture to ask your insertion of this note, because the doctor has ascribed to much more recent observers the credit of priority of description of the clinical signs and effects of this, until recently, unrecognized condition.

I am, yours faithfully,

Lennox Browne.

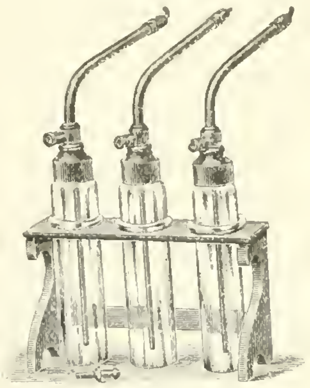
[36 Weymouth Street, Portland Place,
London, W., January 14, 1888.

Severe Blow on the Loin followed by Copious and Long-continued Hæmaturia.—*The Lancet* reports the following case: "A well-grown, muscular laborer was admitted into Middlesex Hospital, December 14, 1886, under the care of Mr. Hulke. He was suffering, at the time of his admission, from concussion of the brain and a scalp-wound, and, in addition to these injuries, he had a bruise on the left loin. He was said to have fallen headlong off a scaffold twenty-eight feet above the ground, and to have struck his left side on a projecting beam. The first urine which he voided contained a very large admixture of blood, and the hæmaturia continued, with slight variations in the quantity of blood, until December 25, 1886, when an evident decrease was first noted, coincidently with the exhibition of acetate of lead in doses of three grains every three hours. Traces of blood did not finally disappear from the urine until January 3, 1887, about which date a small quantity of pus was noticed in it, and a few hyaline casts. With reference to the cause of the hæmaturia, Mr. Hulke remarks that it hardly admits of doubt that the source of the hemorrhage was the kidney, which had sustained some degree of laceration; for the amount of blood was too great to have proceeded from the ureter, and there was not anything to suggest an affection of the bladder. That such lacerations of the kidney are not necessarily fatal without operative intervention is, he believes, abundantly established by experience; and they do not necessarily demand nephrectomy, which should probably be restricted to the severest forms of injury. In this, and in other similar cases, acetate of lead has appeared to him to be decidedly useful."

New Instruments.

AN IMPROVED ATOMIZER.

The accompanying illustration represents an atomizer which has some new features. It is made to be used in connection with the Sass condenser, but may also be worked with the double hand-bulb. When the air is forced into the tube a portion of it passes down into the bottle, presses on the fluid therein, and forces it up to the outlet cap. The larger part, however, passes up the tube to the outlet cap, and there meeting the fluid rising through the inner tube, forces it out in a fine spray. The bottle is of glass, and has a flange upon which it rests in a wooden stand when not in use. The bottle is of a convenient size to be grasped by the hand when an application is made. The tube is of hard rubber, with a platinum tip.



DAVIDSON RUBBER CO.

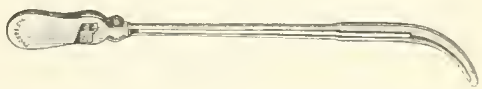
A pressure of only about four pounds is necessary to produce a spray, whereas the forms of apparatus in general use require a pressure of ten pounds or more. The tubes, being of hard rubber, are more durable than those made of glass. The screw-cap is removable, thus allowing of ready cleansing, and the platinum tips are proof against corrosion or softening by any acids that may be used. The caps are screwed on, and cannot by any possibility be blown off, as may sometimes happen when they are merely slipped over the tube. The socket made to receive the tubes can be unscrewed from the bottle whenever it is desired to clean the latter. The atomizer is made by the Davidson Rubber Company, of Boston.

A DILATING URETHRAL SOUND.[1]

By ALEXANDER J. PEET, M.D.,

NEW YORK.

This sound, when closed, is essentially a Weir's sound, twenty-five millimetres in circumference; that is, the upper two-thirds is somewhat smaller than the lower one-third. The instrument, when partially open (as may be seen in the accompanying cut), consists of an ordinary Weir's sound split longitudinally into two halves or arms, which at the extremity of the curved part are united so as to form a joint, the remaining two ends being firmly fixed to the handle of the instrument. A long, narrow bar extends between these two arms, and is connected with them near the curved portion by means of a small set of levers; while the thumb-nut seen in the slot in the handle turns on a screw which forms the upper part



---

[1] This is the sound referred to in my article on An Improved Urethrotome in the Medical Journal of May 15, 1886, the description of which has been deferred until the present time.

of this central bar. The instrument is opened and closed by simply turning this thumb-nut to the left or right. On this nut is a French scale extending from twenty-five to forty millimetres, and the thread of the screw is so cut that one complete turn of the nut opens the sound to forty millimetres. I have had a smaller sound constructed upon the same principle, which is ten millimetres in circumference when closed, and twenty-five when open. These two instruments, therefore, accomplish the same amount of work as a set of thirty ordinary sounds.

The great and obvious advantages obtained by the use of this instrument are as follows:

1. It is much more economical to buy one or two of these instruments than it is to buy a set of thirty ordinary sounds.

2. Among physicians who believe that dilatation is the proper method for treating strictures, this instrument is peculiarly advantageous, since after once introducing it the urethra can be dilated as much or as little as is desired without inflicting the injury and pain on the delicate mucous membrane that the repeated introduction of different-sized sounds is so apt to do, even in the hands of the most skilful.

3. This instrument can also be used very advantageously by surgeons who think that all strictures must be divided to effect a cure; for after division it is necessary for several days to introduce large sounds, in order to prevent the stricture from closing during the process of healing, and thus leaving the canal in as contracted a state as before the operation. Particularly is this the case if the stricture is not completely divided. By one introduction of this instrument at any time during the healing process the stricture can be torn open with little or no pain, especially if a few drops of a solution of cocaine are injected prior to the operation.

4. Another great advantage in using this instrument is that any portion of the urethral canal can be dilated without materially affecting the remaining portions.

5. Inasmuch as several articles have appeared of late in our medical journals as to the inadvisability of meatus-cutting, it may not be amiss to say that this instrument will be of especial value to those surgeons who believe that the meatus should be cut but rarely, since the sound, when closed, can be introduced through a meatus of ordinary size, and the canal beyond can then be dilated to forty millimetres, if required, without materially stretching the meatus.

174 West Fifty-eighth Street.

The Cellulo-microbian Warfare.—Throughout our lives there is a constant miniature battle in progress within our bodies, the elements of health waging fierce warfare on the invading microbian elements of disease. When in perfect health, the body-cells are successful in the contest, destroying the injurious microbes as fast as they enter; but let some condition impair the vigor of these cells, our body-guards, or introduce some microbe with which they are unable to cope, and the stream of battle turns about, and disease is rampant. These cells, possessing the power of absorbing and digesting microbes, are called by Metschnikoff "phagocytes," and are not destined for the destruction of microbes alone, but also for the absorption and removal of dead or degenerated tissue. M. Metschnikoff has made researches on transparent animals, such as daphnea, which are often invaded by spores of the yeast family. These spores, after entering the intestine with the food, escape into the cavity of the body of the animal, when a struggle to the death begins between them and the white corpuscles, which, singly or in groups, absorb and destroy the spore, thus saving the life of the daphnea. M. Metschnikoff claims that essentially the same struggle is forever continuing in the body of man, only on a more complicated scale, and divides our standing army of protective cells into "microphagi" and "macrophagi."—*The Weekly Medical Review.*

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from January 29 to February 4, 1888.

Page, Charles, Lieutenant-Colonel and Surgeon. To be Assistant Surgeon-General, with rank of Colonel. November 17, 1887.

McKee, James C., Major and Surgeon. To be Surgeon, with rank of Lieutenant-Colonel, November 17, 1887.

Girard, Alfred C., Captain and Assistant Surgeon. To be Surgeon, with rank of Major, November 17, 1887.

Raymond, H. I., First Lieutenant and Assistant Surgeon. Ordered to Fort Bidwell, Cal.

Fisher, W. W., First Lieutenant and Assistant Surgeon. Ordered to Presidio of San Francisco, Cal. S. O. 25, A. G. O., January 31, 1888.

Medical Items.

Contagious Diseases—Weekly Statement.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 4, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	7	2
Scarlet fever	147	24
Cerebro-spinal meningitis	1	1
Measles	46	8
Diphtheria	166	39
Small-pox	5	0
Yellow fever	0	0
Cholera	0	0

The Term "Malignant."—The resemblance between the innocent tumors and the cancerous may seem to indicate such close relation that they ought to be regarded as of essentially the same nature. But I believe that an unlikeness indicating differences yet more essential may be observed in them, and it is expressed in our calling them severally innocent and malignant growths. Malignant is nearly synonymous with cancerous; and though the name is sometimes treated with disrespect, as being figurative and without scientific meaning, yet, as an expression of certain qualities shown in the method and course of the diseases to which it is applied, it is neither unfit nor, I think, unmeaning. For the qualities which the name "malignant" indicates are far more distinctive, more surely diagnostic, of this group of diseases than are the minute structure and chemical composition of the diseased parts, or even than the method of their growing; and in this is an example of what we must hold in the study of all diseases, for pathology is a part of biology, and not derived chiefly from the study of anatomy and chemistry.—Sir James Paget, in the "Morton Lecture on Cancer."

Glassblowers' Syphilis.—Professor N. De Smet, of Brussels, in commenting upon a case of syphilis occurring in the mouth of a glassblower, referred to several epidemics which have been reported as having occurred among artisans of this description. He said that only two plans for preventing these outbreaks had been devised, viz., giving a separate movable mouth-piece to each man, and instituting frequent, rigorous, and periodical inspection of the persons of the employés. The first plan is always declared by the workmen to be impracticable, from the loss of time which would be occasioned by fitting the different mouth-pieces on the tubes. The second would, of course, be resisted by the men, but he thinks their objections could be overcome by showing them the danger to themselves and their families which arises from the present system.—*The Lancet.*

A Warning for the Overworked.—One of London's most successful physicians, a few months before his death, in conversation with a friend, said: "You see me, at a little over forty years of age, in full practice; my rooms are full, and I am making several thousands per annum, and if I die to-morrow I do not leave as many hundreds to my family. All this I have done by sheer perseverance, unceasing hard work, and no holiday. But I am to-day a wreck. I have fatal disease of the heart, the result of anxiety and hard work. I know I cannot live many months, and my parting advice to you is this: 'Never mind at what loss, take your six weeks' holiday. It may delay your success, but it will insure its development.' Otherwise you will find yourself at my age a prosperous practitioner, but a dying man."

Large Nævus in an Unusual Location.—Dr. A. McShane records the following rare case: "The patient was a young white man, aged twenty, in good physical condition. Five years ago a friend, while looking at his back teeth, observed a large swelling on the right side of the soft palate. In October, 1887, there was a large purplish bulging in that locality, involving the pillars of the fauces and the uvula, which is three-fourths of an inch long, and very thick. Immediately to the right of the uvula is a slightly elongated, blackish mass, projecting downward, which consists of distended veins. All over the surface of the swelling numerous dilated blood-vessels are seen, giving a mottled, purplish aspect to the tumor. The swelling is soft. The patient does not know how long he has had it; he himself first noticed it five years ago, and it was as large then as it is now. The swelling is a large nævus, occurring on the mucous membrane of the soft palate and fauces. It causes no inconvenience in swallowing or speaking, but swells a little when he gets a cold."—*New Orleans Medical and Surgical Journal*, December, 1887.

Better than the Doctor's Advice.—A man met his doctor on the street and complained of rheumatic pains, for which the doctor recommended him to take a pinch of "nitrate of potash" two or three times a day. Shortly afterward he met the doctor again, and in reply to a question regarding his health, remarked, "Oh, I'm getting well, doctor; but 'tain't your medicine. I tried that for some time, till a neighbor told me of something he took for his rheumatism—a very simple remedy. I tried it, and it does me a great deal of good." "What is it?" said the doctor. "Oh, it's simple; I'm afraid you'll laugh at me if I tell you." The doctor promised to control his risibles, and the patient, after much urging, informed him that it was "saltpetre." The doctor's smile was longer than the street.—*Chemist and Druggist.*

The Renal Glomeruli in Disease.—In the various forms of inflammatory and degenerative disease to which the kidney is liable there has been assigned by all the more recent authorities a very considerable share to the Malpighian corpuscles. Since Klebs drew attention to "glomerular nephritis" it is remarkable how the tubular lesions have gradually taken a secondary place. Dr. Hansemann, one of Professor Virchow's assistants, has published an article on the subject, which tends, if anything, to limit the sphere of the changes in the glomerular tufts (*The Lancet*). His pathological study is based on the examination of one hundred and twenty cases of nephritis, arising under very varied conditions. He prefaces his account of the results obtained in these morbid specimens by a statement of the normal histology of the Malpighian body which departs slightly from the usually accepted teachings. Bowman's capsule, which is continuous with the basement membrane of the convoluted tubule, is composed of a single layer of cells, the nuclei of which may or may not be centrally situated. The tubule is not constricted at its termination, but expands rapidly in a funnel-shaped manner; while developmentally the capsule is formed directly from the curvation of a tubule, and in the same way the epithelial layer covering the glomerular loop is formed. The space between the capsular and glomerular epithelium is filled with fluid, which, according to Dr. Hansemann, can be seen in hardened specimens to be traversed by a fine filamentous net-work. He does not agree with Drasch's division of the glomeruli into a larger set placed centrally, and a smaller-sized set placed peripherally, in the kidney. For, although it is evident that these bodies vary much in size, there is no such manifest separation in structure and situation as Drasch implies. The glomerular investing membrane is, according to Hansemann, merely a layer of cells with scanty nuclei, and cannot, as usually stated, be separated into a basement membrane and endothelium. He also declares that connective-tissue elements are very scanty in the glomerular tuft, being mainly limited to the region of the afferent and efferent vessels; while he disputes the statement of Babes that these vessels at their points of entrance and exit are dilated in an ampullary manner, or that such degenerative processes as amyloid and sclerotic changes select these positions for their starting-points. The pathological portion of Dr. Hansemann's essay deals in turn with certain questions respecting the rôle of the Malpighian body in renal disease, and the replies to these questions are based entirely upon his own histological studies. The first is as to whether these structures take part in every affection of the kidney, and if so, are they attacked simultaneously with or before the rest of the organ? He shows that although in many cases of parenchymatous nephritis, as well as of other diseases, the Malpighian corpuscles are involved, yet that cases do occur in which these corpuscles (even in nephritis) may remain unaffected. In a few instances they are so much affected as necessarily to influence the nutrition of the rest of the renal substance; but it is very rare and quite exceptional to find that glomerular lesions are the first to appear. Another point is as to the part played by nuclear proliferation in the glomerular change. This is always more marked in young subjects, in whom the nuclei are normally more abundant. However, there is undoubted evidence of proliferation of epithelia, more especially of that covering the tuft, besides leucocytal infiltration, which is liable to be mistaken for the former. Further, he denies that the pathological changes—*e.g.*, amyloid degeneration—to which the glomerular tufts are liable afford any evidence that their constituent vessels are provided with a special endothelial lining, as Langhans asserts. On the contrary, he finds that the delicate walls of these capillaries are simply composed of epithelium. In disease of the Malpighian bodies, it would seem that very extensive changes in the direction of swelling, proliferation, and shedding of the epithelial lining of the capsule and tuft may take place without any apparent lesion of the vessels. This, of course, does not apply to amyloid change, which commences in the vessels. Lastly, in speaking of the relation of glomerular lesions to those of the rest of the kidney, he distinctly discards the doctrine of a primary glomerular nephritis. He quotes Cohnheim to the effect that it is inconceivable that the several vessels and tubules of the kidney should share equally in the work of secretion, and that inflammation should attack simultaneously all the glomeruli or all the tubules. It accords with experience that nephritis does not involve the whole kidney to an equal extent, or both kidneys in the same degree. And there is sufficient evidence adduced to show that there is no relation between the extent of disease in the glomeruli and that in the rest of the kidney;

although it necessarily follows that where a Malpighian body is so diseased as to be functionally destroyed the tubule in connection with it must be more affected than is the tubule connected with a less damaged glomerulus. In amyloid degeneration there is, besides the malnutrition induced by interference with blood-supply, a probability that the tubule connected with the affected glomerulus atrophies from disuse, being no longer required to fulfil its function. The polyuria of amyloid disease will have, then, to be explained in another way—but Dr. Hansemann does not proffer any such alternative.

UTERINE MYOMA TREATED WITH HYDRASTIS.—Dr. Schmidt, of Prague, has treated with remarkable success a case of long-standing myoma of the uterus, accompanied with copious hemorrhage, by means of tincture of hydrastis canadensis. Twenty-five drops were given four times a day for three or four months. During this period the hemorrhage stopped, the menstrual periods became normal, and the tumor decreased very markedly in size.—*Lancet.*

HAP-HAZARD MEDICATION.—*The Medical Register* inveighs against the too common practice of prescribing in a hap-hazard way. It says: In the medical profession how many are striving to fight disease with weapons of which they are absolutely ignorant, prescribing they know not what, simply because some enterprising manufacturer has told them that his compound is an excellent thing, and has almost miraculous curative powers in this or that disease. That the inducements to this sort of hap-hazard prescribing are exceedingly numerous is patent to everyone who takes the trouble to glance through the advertising pages of many papers and periodicals, or looks over the mail of any physician. They are all filled with advertisements of these wonderful (!) compounds, and the mail is largely made up of circulars and pamphlets descriptive of the powers of these selfsame "life preservative, death preventative" mixtures. While they discourse at great length upon the wonderful curative powers of these remedies, scarce a word is said as to the *composition* of the preparation. Perhaps one or two lines of small-sized type may be devoted to the publication of a so-called "formula," in which anywhere from three to a dozen powerful drugs are enumerated as entering into the composition of these "triumphs of pharmacy." An instance of this occurs in the formula of a very extensively advertised preparation, which informs us that the compound (of course, ending with an *ine*) contains "the essential constituents" of six powerful drugs, but not one expression as to the proportions of these drugs to each other, or to the ounce or pint of the preparation. The physician who uses this is prescribing in the most hap-hazard way. He is little better than an empiric. Ignorant of the quantities of the drugs contained in the preparation, which obliges him to confine himself to the dose prescribed by the manufacturer, he is unable to graduate the dose to the requirements of the case, and if, by chance, his patient recovers, he cannot tell which of the drugs, if any, contributed to that recovery. His knowledge of the treatment of disease is not increased; neither has he gained in experience. Science is not benefited by the use of these compounds. They add nothing to the progress of medicine. On the contrary, they are a hinderance, a positive injury to it, for their use lowers the physician into a quack, and changes the pharmacist into a mere vender of merchandise. The treatment of disease is a difficult matter at best, and needs all the attention we can give to it, instead of shutting off what light we have by the use of preparations of which we know nothing beyond what the manufacturer, anxious to dispose of his wares, chooses to tell us. How may this state of affairs be overcome? There are several ways, but there is only one positive means of eradicating this evil. Let every member of the profession refuse to use, or in any way to give support to any and all preparations of which the manufacturer does not, or will not, furnish complete information regarding the ingredients, their quantities, and mode of preparation. Some of these compounds are, no doubt, excellent preparations and, it may be, improvements upon what we already possess, but they are lost to science because of the secrecy concerning their mode of preparation. Let the manufacturers throw around their products all the protection by furnishing good and reliable preparations. Let them furnish true "working formulæ" of their ingredients, and they will then be a help, instead of a hinderance, to the progress of medical science.

THE DIGESTION AND TEMPERATURE OF THE SNAKE.—Mr. H. M. Phipson, of Bombay, has made some curious observations on the physiology of the Indian rock snake (*Python molurus*). "During the twelve months between May 27, 1886, and May 20, 1887, the snake ate twenty-three rats, three hens, three crows, and one hawk. In the hot months the period of digestion averaged about eight days, whereas in the cold weather it became much slower, in one instance being thirty-eight days. During the cold weather, for a period of one hundred and thirteen days, the snake refused food, and remained in a very sluggish and sleepy condition. During this period of the hibernation the temperature of the reptile fell from 82° normal to 73°, a fall of nine degrees. The snake shed its skin four times in the course of the year; three times in hot weather at an interval of two months, and once after it had recovered from its hibernation."—*Journal of Comparative Pathology.*

JAMBUL IN DIABETES.—Mr. J. Munday, of Poona, writes to the *British Medical Journal:* "After several years' experience in this country with 'eugenia jambolana,' in diabetes, I have found it does not lessen the amount of sugar secreted, but does immensely reduce the quantity of urine, thereby relieving (quite) the irritability of the urethra, and giving the sufferer a complete night's rest. The fruit grows plentifully. The seeds ought to be let dry in an open vessel, the kernels removed, pulverized, and the quantity of one seed taken thrice daily. In forty-eight hours the diminution of urine takes place. Codeia in a pill of half a grain, taken with the above thrice daily, holds the secretion of sugar in check, and with certain restrictions in diet affords the patient apparently permanent relief, and need not interfere with a useful career."

NOTES ON PROGRESS OF ABDOMINAL SURGERY—*Laparatomy for acute suppurative peritonitis.*—The treatment of acute suppurative peritonitis by laparotomy and copious injections into the abdominal cavity was brought under notice at a recent meeting of the Clinical Society by Mr. Barwell, who, in his remarks on a successful case under his own care, claimed for Mr. Hancock the first conception of the idea of opening the abdomen for acute peritonitis. At the same meeting two interesting cases, in which similar treatment had been practised with good results for tubercular peritonitis, were reported by Mr. Knaggs and Dr. Kilner Clarke, of Huddersfield. The discussion on these papers, though maintained with much ability, was confused and unsatisfactory, from the fact that the treatment of two really different affections—one being acute, the other chronic—was made the subject of the same debate.

Splenectomy.—That abdominal section is now performed under much improved conditions may be shown by the latest results of splenectomy. Dr. Leonard, of Philadelphia, has recently reported a case of successful removal of an hypertrophied spleen, and has asserted that, in twelve of seventeen cases that have been recorded since the year 1881, this operation had good results. Other successful cases have during the year been published by Dr. Myers, of the United States, and by Dr. Severeanu, of Bucharest; and in the last number of the *Journal* mention was made of a still more recent instance, in which an enlarged spleen had been successfully removed by Sir Spencer Wells. Two cases of successful treatment of cystic growths of the pancreas by abdominal section, incision, and drainage have been put on record by Dr. Bull, of New York, and by Professor Küster. In concluding this review of the latest contributions to peritoneal surgery, reference may be made to Mr. Meredith's case of a large omental lipoma, weighing over fifteen pounds, successfully removed by abdominal section, and to an instance of a very much larger fatty growth similarly treated, but with a fatal result, by M. Terrillon, of Paris.

Renal surgery.—In renal surgery much has been done toward establishing the indications of the operative procedures that have been so often practised during late years. The lumbar and extra-peritoneal operation is still preferred in most quarters to abdominal section. In London special attention seems to have been paid during the year to the treatment of calculous disease of the kidney. It has been shown by Mr. Godlee that sympathy may exist between the two kidneys in case of disease originating in one organ, and that suppuration around a damaged kidney may cause albuminuria and an abundant production of casts in the secretion of the opposite and healthy organ. Israel, of Berlin, has lately put on record a case of cancer of the kidney in a young subject, in which case the diagnosis was established and nephrectomy performed while the disease was in a very early stage, and the diseased organ of normal size.—*British Medical Journal.*

Remarkable Hereditary Longevity.—Dr. A. Huntington of this city writes: "It may be of interest to see how strongly longevity in families is marked in some instances, and in some portions of the world perhaps more strongly than in others. As an illustration of this I give you the exact copy of a most remarkable family record which came recently under my notice as medical director of one of the large life insurance companies of our country. The individual to whom this wonderful record attaches is a native of Bulgaria, and is now upward of sixty years of age. The truthfulness of the record is vouched for. The father died at the age of eighty-nine, the mother at the age of eighty-three; the father's father and the father's mother reached the ages of one hundred and five and one hundred and twenty respectively; the mother's father and the mother's mother reached the ages of one hundred and sixteen and ninety-five respectively; there are five brothers and four sisters, comprising, with the individual himself, the entire family, and these are all living and in excellent health, ranging from thirty-five to fifty-eight years in age. One of the sisters is reported as having borne fourteen children, and another sister eleven children, *all* of whom are living, and several have children of their own. Another sister, still, has borne eight children, all living; but the fourth sister, although married, has remained barren. This is one of the most remarkable family records it has ever been my lot to see; but I am informed that such records are not altogether infrequent in the rural towns of Bulgaria, and that some portions of Turkey also furnish equally remarkable family records. I suppose the reasons are to be mainly found in the combination of the climate and habits of the people, which latter are very different from the rushing, nervous restlessness of our own American people."

New Surgical Operations.—Dr. J. A. Moore writes from Reichenberg, Bohemia (Austria), to the *Albany Medical Annals*: "I have seen some few operations here that I never saw or heard of at home, nor in any of the books. One by Pawlik, for incontinence of urine in women, consists in removing a triangular strip the whole length of the urethra, and quite deep, on one or both sides. We have a case under treatment here now; have done the operation on one side, and shall do it on the other in a few days. The doctor here had never seen it. Another is by Gertie, the first assistant to Professor Albert, for amputation at knee-joint. In this operation the patella is brought to the under surface of the femur, making a round-end stump, with all scar behind. Another for stricture of rectum, by opening into descending colon in front (left side) and dilating through. Another for stricture of œsophagus, performed by doing the ordinary gastrotomy, and dilating by passing sounds through. Another, and a beauty, is for bunions, done by cutting between the great and second toes (under surface) and removing the second metatarsal bone, sometimes two, then strapping the toe straight. The result is grand." Dr. Moore evidently sees so much which is new that he does not have time to cultivate his literary style.

Comparative Statistics of the Treatment of Diphtheria.—Dr. Lunin, of St. Petersburg, made comparative trial of various remedies in the treatment of diphtheria in the Oldenburg Hospital, with the following result: Cases, 296; percentage of deaths, 55.

Fibrinous form.		Septic phlegmonous form.		General result.
Per cent. of Deaths:		Per cent. of Deaths:		Per cent.
By turpentine	8.30	By turpentine	81.00	43.4
By resorcine	20.00	By resorcine	89.50	65 0
By sublimate	30.20	By sublimate	92.50	45.0
By chinoline	31.60	By chinoline	100.00	53.0
By ferri perchlor	32.60	By ferri perchlor	76.50	56.0
By bromine	46.70	By bromine	88.90	69.7

—*Journ. Am. Med. Association.*

Infant Morphiomaniacs.—Children born of morphia-eating mothers are practically, says Erlenmeyer, morphia-eaters, and during the first days of their life, unless morphia is given them, are very apt to suffer collapse. This condition may end in death, and seems to be parallel to the sudden giving out of the system which sometimes follows the sudden withdrawal of the alkaloid in adults.

Lobar Arrangement of Phthisical Lesions.—An examination of the literature of pulmonary phthisis will show how little attention has been paid by most writers to the question of the exact distribution of the lesions in the lungs and their relation to the chest-wall. Dr. Kingston Fowler has gathered together some facts of importance, and in *The Practitioner* gives us the outcome of his own experience. He believes that there is a definite mode of extension of the lesions of phthisis through the lungs, and has found great assistance in the diagnosis and valuable aid in the prognosis from a recognition of this fact. We agree with Dr. Fowler in thinking that there probably is in most cases of phthisis a distinct "line of march." The extreme apex of the lung is not often the site of the primary lesion; it is situated from an inch to an inch and a half below the top, and rather nearer to the posterior and external borders. Lesions in this region tend to spread in the first instance backward, possibly from inhalation of the virus while the patient is lying down. This accounts for the fact that an examination of the supra-spinous fossa will often give certain evidence of the presence of disease when the physical signs in front of the chest have left some doubt. From this primary focus, which in front corresponds either to the supra-clavicular fossa or to a spot immediately below the centre of the clavicle, the lesions often first spread downward along the anterior aspect of the upper lobe, about three-fourths of an inch within its margin, frequently occurring in scattered nodules, separated by an inch or more of healthy tissue. The second and less usual site of the primary affection of the apex corresponds on the chest-wall with the first and second interspaces below the outer third of the clavicle. The lines of extension are usually downward and backward. The lower lobe of the lung primarily diseased is usually affected at a very early period. The site of the primary infiltration of the lower lobe is generally situated about an inch below the upper and posterior extremity of the apex of the lower lobe, and this situation corresponds on the chest-wall to a spot opposite the fifth dorsal spine midway between the border of the scapula and the spinous processes.—*The Lancet.*

Hydatids in Bone.—An instance of this rare affection was observed by Dr. Leacock, who reports it to the *Australasian Medical Gazette.* A man, aged forty, was troubled with his left knee ever since his twelfth year, when he received a blow. About twenty years ago he was kicked by a horse on the same knee. Some thirteen years later symptoms of pain and swelling came on after walking. They were so severe as to necessitate medical treatment, which was continued for six months, the patient being more or less confined to bed during that time. Since then—that is, for the last seven years—there has been inability to completely straighten the limb, frequent pain, and permanent though slight enlargement of the joint. The patient came under Dr. Leacock's care about four months ago, through having struck the knee violently against a post. He saw him a couple of hours after the accident, when he was suffering very acute pain in the joint. For a fortnight he kept his bed, with all the usual local symptoms of acute synovitis, but little or no constitutional disturbance or rise of temperature. At the end of that time, the pain having greatly subsided, he left his bed on crutches, but could not put his foot to the ground, and, the pain gradually returning, after two or three weeks he was compelled to take to bed again. All the usual means for obtaining absolute rest to the joint were adopted. Extension, which usually gives relief in acute joint disease, in this case seemed only to increase the pain. There were no symptoms, either local or general, of suppuration. There was only a slight increase of swelling about the knee; very little effusion in the joint, the permanent seat of pain being referred more particularly to a spot on the inner condyle of the femur. In addition, there were the usual electric-shock pains and startings, aggravated at night. Finding, after about a month's treatment, that absolutely no improvement took place, that the patient's health was beginning to break down from constant pain, and that he himself was anxious for relief at any risk, the author suggested resection, or amputation, if found necessary. On opening the joint, he found a small amount of flocculent lymph, slight erosion of the articular cartilages, and on digital examination a perforation admitting the tip of the finger, between the condyles of the femur, apparently communicating with a cavity in the end of that bone. There was chronic thickening of the ligaments and fibrous tissue of the joint, but no pus; nor did he see any hydatid cysts in the joint, and he was certainly not expecting them. On applying the saw to the condyles of the femur, the instrument did not meet with the usual resistance; the bone, in fact, was a mere shell, in some parts scarcely thicker than paper. Such being the state of affairs, amputation was the only resource. On examining the removed limb, the lower end of the femur was found hollowed out into one large cavity, stuffed full of hydatid cysts, from the size of a small pea to nearly an inch in diameter. The cancellous structure in the head of the tibia was undergoing fatty degeneration, and in the popliteal space was an ounce or more of broken-down soft tissue, evidently a commencing abscess, though not yet converted into pus.

Cholera and Milk.—An instructive example of the facility with which milk may become the medium for the propagation of a zymotic disease is afforded by a limited epidemic of cholera which occurred on board a sailing ship, the Ardenclutha, lying in the port of Calcutta. Dr. W. J. Simpson, the health-officer of Calcutta, investigated the outbreak with great care, and offers strong evidence that the outbreak was not to be traced to any peculiar climatic condition, to the state of the ship, to the water, or to any circumstances connected with the visits of the men on shore. Pursuing the inquiry, it was ascertained that ten of the men had used milk supplied by a native who visited the ship daily; of these ten men, nine were affected; four died of cholera, and five had severe diarrhœa. With regard to one other man, who was the last to suffer from cholera, it was doubtful whether he drank any of this milk or not; as he sickened after the others he may have contracted the disease from an earlier case. Only one man who drank the milk escaped, and he only took a very small quantity. The native who supplied the milk kept one cow, which was in good health, but he frankly admitted that the milk he supplied to the sailors contained about twenty-five per cent. of added water; and it also came out that several of his neighbors had suffered from cholera. A case had been imported on March 2d; the dejecta from this patient drained into the tank on which the milkman's house stood. The first case among the milkman's neighbors occurred on March 7th; the first case of diarrhœa among the crew of the Ardenclutha on the same day, and the first case recognized as cholera two days later. This, taken along with the admission that water was added to the milk, and that, with one exception, the remainder of the crew, fourteen in number, who had not drunk the milk, did not suffer from cholera or diarrhœa, leaves very little doubt as to the origin of the epidemic. The milk was clearly the connecting link between the epidemic in the hamlet and on board the ship, and it was without much doubt rendered infective by the addition of the tank-water fouled by the dejecta of the imported case. The investigation also shows that cholera, while prevailing in a distant locality, may be established simultaneously at two widely different places, and yet be due to a common cause which is preventable.—*British Medical Journal.*

Sterility in the Male.—Dr. Kehrer, of Heidelberg, has recently published some researches on this obscure subject in a work entitled "Beiträge zur Klinischen und Experimentellen Geburtskunde und Gynäkologie." To forty already reported cases of sterile marriages where he had examined the semen, he has added fifty-six more. In 3.12 per cent. complete impotence was certain; in 30.21 per cent. the semen did not contain spermatozoa (*Azoöspermia*); in 11.45 per cent. these organisms were deficient in quantity (*Oligozoöspermia*); and in 55.20 per cent. they were present in abundance (*Polyzoöspermia*). Among the cases of azoöspermia, in many instances no cause for the anomaly could be traced; in a fifth, masturbation had avowedly been practised; in more than two-thirds, the subjects had suffered from gonorrhœa, but disease of one or both testicles could not be detected in many of these patients, so that Dr. Kehrer suspects other complications besides disease of the epididymis, such as obstruction of the ejaculatory duct through prostatitis, or fatty degeneration of the tubuli seminiferi. The proportion of subjects where there had been gonorrhœa was the same in the cases of oligozoöspermia, where yet a chance of fruitful coitus remained, while among the sterile men where polyzoöspermia was discovered, only half as many had been subject to gonorrhœa. Dr. Kehrer believes, judging from his researches, that in at least a third of the cases of sterile marriages the husband was the party at fault, and gonorrhœa was the primary cause of the barrenness. Here it must be remembered that, unfortunately, that disease is extremely common among young unmarried men, and in making researches in long series of fertile marriages, a large proportion of the husbands would probably be found to have suffered from gonorrhœa. Noegerrath fell into a doubtful line of argument somewhat like that of Dr. Kehrer, and Bumstead, among others, exposed the fallacy. Dr. Kehrer believes that other sources of sterility will yet be discovered, such as influences directly prejudicial to the germ-cell or sperm-cell.

THE NERVOUS SYMPTOMS, LOCAL AND REFLEX, ARISING FROM THE DISPLACEMENTS AND INFLAMMATIONS OF THE UTERUS AND ITS APPENDAGES.[1]

By GRACE PECKHAM, M.D.,

NEW YORK.

In the scant literature which has been written upon the nervous affections dependent upon abnormal conditions of the uterus and its appendages, there has been presented, for the most part, an array of unusual and startling cases, until the profession, and the public, too, as for that matter, have come to feel that a woman's organs of generation are seldom in a state of perfect health ; rather more, that they are centres from which emanate the most terrible and awful nervous explosions. This is, indeed, sometimes true, but not nearly as often as one is led to suppose from the articles which from time to time come from the pens of our most eminent gynecologists, illustrated with cases numbering from two or three to a dozen or more, setting forth weird reflex neuroses starting from the genital tract.

For the last four years, in taking the histories of my gynecological cases, I have had in view the finding out of how extensively and in what directions the nervous system was implicated in diseases of the uterus and its appendages. This paper, therefore, has not for its object the presentation of unusual and bizarre cases. Out of over two thousand cases, I have selected for analysis about five hundred. I have set aside any in regard to which there might arise some question as to the diagnosis, either of the disease of the uterus and its appendages or the dependence of the disturbances in other parts of the body upon pelvic trouble. I cannot, as it is, claim absolute accuracy for the table which I have prepared, but I have endeavored to make it as nearly so as possible. It can be easily understood that it is difficult to gather together cases which are typical and uncomplicated with other troubles. To simplify my already too complex subject as much as possible, I have excluded from consideration all the nervous disturbances of menstruation and the menopause, and those arising from neoplasms. The symptoms classify themselves naturally into four distinct groups: 1. Those of the pelvis. 2. Those of the alimentary canal. 3. Those of the head. 4. General nervousness, including hysteria.

Besides these, there remain a few peculiar symptoms which do not readily fall into this classification, but should be noted.

This may not be the most scientific way of regarding the symptoms, but for purposes of study and contrast it has seemed the most practical.

In complete prolapsus we find that out of 37 cases 25 suffered no pain, nor experienced any nervous disturbance. The trouble was entirely that of a mechanical inconvenience. Two had no pain, but great dyspepsia, which possibly might not be attributable to the nervous disturbance ; 5 had pain only in the hypogastrium ; in 1 the pain was referable to the whole pelvic region, 1 to the right side, and 1 to the left side ; 2 had lumbar and sacral pains ; 1 suffered from general nervousness.

In prolapsus of the second degree, 15 had pain referable to the whole pelvis, in 3 of which the pain was of a bearing-down nature ; in 2 it was sticking in character ; 1 complained of pain in the hypogastrium alone ; 5 had pain in the back, and 4 in the left side ; 2 had flatulence, and 2 felt as if something were moving in the abdomen, a sensation which gives rise to the notion that pregnancy may exist ; 2 had general headache ; 1 had headache referable to the vertex ; 1 had dizziness.

In prolapsus of the first degree, of the 20 cases 8 had pain referable to the whole pelvic region, 4 to the left side, 4 to the lower lumbar and sacral regions ; 1 had flatulence, 2 had dyspepsia, 1 had disturbance of the general nervous system.

Considering, also, in this connection, anteflexion with prolapsus, there are 6 cases, and no nervous disturbance outside of the pelvis, the pain occurring in the whole pelvis and on either or both sides. In retroflexion with prolapsus (9 cases), 4 were troubled with headache.

In 97 cases of prolapsus, 37 were of complete prolapsus, 20 were of the first degree, 25 were of the second degree, 6 were of anteflexion with prolapsus, and 9 were of retroflexion with prolapsus.

In the analysis of these cases it is shown that in only 16 have the symptoms extended beyond the pelvis ; that they are mainly referable to the whole pelvis or to the left side ; that the cases of the first and second degree give rise to pain, owing to the dragging and pulling away of the organ from its attachments, but when this is accomplished and complete procidentia has become a fact, pain is no longer a prominent symptom.

The cases in which anteversion occurs, uncomplicated with inflammation or other troubles, and of sufficient degree to be considered pathological, are not very numerous. There were 8 such to be found : One had no pain, except menstrual ; 4 had pain in the whole pelvis, 1 complaining of it especially in walking, another saying that it reached to the shoulders ; 2 had pain in the right side ; 1, in both sides. Of these, 2 complained of headache, and 1 of dizziness.

Retroversions are more numerous. Of the 34, 6 had no pain (came for dysmenorrhœa) ; 16 had pain in the whole pelvis ; 4, in the left side ; 1, in the hypogastrium ; 2, in the back ; 1 had headache, and no other disturbance ; 4 had general headache ; 2 complained of dizziness ; 2, of creeping sensations in the back and cold perspiration.

Of 32 cases of anteflexion, 17 complained of pain in the whole pelvis ; 2, of each side ; 1, of both sides ; 1, of hypogastrium ; 5, of the back alone or of the back and sides together ; 1, of flatulence ; 1, of dyspepsia ; and 4, of general headache. Two had general nervousness ; 1 was subject to fainting attacks ; 2 were hysterical.

In retroflexion, of the 39 cases 5 complained of no pelvic pain ; 20 had pain referable to the whole pelvis ; 2, pain in the right side ; 4, in the left side ; 1, in both sides and back ; 1, in the hypogastrium ; 6, in sacral and lumbar region. The intestinal disturbances were peculiar ; 2 felt the flutterings as if pregnant ; 1 felt as if "the wind worked up to her head ;" 4 had dyspepsia ; 3, vomiting ; 11, general headache ; 1, frontal headache ; 3 had dizziness ; 3 had hysteria ; 3, general nervousness ; 1, cold perspiration.

In the 42 cases of versions 19 had nervous disturbances extending beyond the pelvis ; and in the 71 cases of ante- and retroflexions, 20. The flexions act more seriously on the general nervous system than any of the other purely mechanical displacements. The circulation of the uterus in flexions is so impaired that they cannot exist long without giving rise to inflammatory conditions which bring with them pelvic pains. Shortly the circle of disturbance spreads to the periphery; the digestive functions become disturbed and neuralgias are invoked.

---

[1] Read before the Section on Neurology of the New York Academy of Medicine, January 13, 1888.

Passing on to the inflammatory conditions, we will first consider endometritis. I have excluded from this list a large number of cases in which the only symptoms were those of menstrual derangement, either dysmenorrhœa or menorrhagia due to fungoid growths. Of the 45 cases 27 had pains referable to the whole pelvis; 3 had pains running down the thighs; 1 had pain in the right side, and 9 had pain on the left; 8 had pain in the sacral and lumbar regions, and 2 in the hypogastrium; 2 had dyspepsia; 3, nausea; 8 had general headache; 1, frontal headache; 3 complained of dizziness; 3 had general nervousness; 3 had hysteria; 1 had paræsthesia; 1, general neuralgia; and 1 complained of trouble with the eyes.

In 29 cases of endometritis with anteflexion, 19 had pelvic pain; 3 had pain in the right side; 1 in hypogastrium, and 5 in sacral and lumbar regions; 6 had flatulence; 2, dyspepsia; 8, general headache; 1, dizziness; 3 were hysterical.

In the 37 cases of retroflexion with endometritis, 21 had pelvic pain; 2 had pain extending down the legs; 2 had pain in the right side; 4 had pain in the left side; 2 had pain in the hypogastrium; 3 had pain in the lower lumbar and sacral regions; 8 were dyspeptic; 5 had nausea; 6 had general headache; 1, headache at the vertex; 1, occipital headache; 1 was dizzy; 1 complained of the eyes; 1 had melancholia; another had chilly sensations.

In the 111 cases, 45 were of endometritis; 29 were of endometritis and anteflexion; 37 were of endometritis and retroflexion. Of these, 44 had symptoms extending beyond the pelvis.

Of 26 cases of contractions and chronic inflammations of the broad ligaments, in 1 case both ligaments were tender and contracted, but the pain was referred to the left side. In 1 (left side) there was no pain. In 2, where the trouble was on the left side, the pain was located upon the right; and, *vice versa*, in the cases where trouble was in the right broad ligament, the pain was on the left. In 13 cases both the trouble and the pain were on the left side, and in 2 others the left side and back were seats of pain. Two with trouble in the right side had pain in the back, and 4 with trouble in the left side had also pain in the back. Three had flatulence; 2, dyspepsia; 1, nausea; 3, general headache; 1, frontal headache; 3, dizziness; 1 had hysteria; 1, paræsthesia; 1, trouble with eyes; and 1, hiccough.

Of 6 cases of anteflexion, complicated with trouble in the broad ligaments, 2 had pain in the right side; the remaining 4 had sharp, burning, cutting pain in the left side; 1 only suffered from dizziness.

There were 16 cases of retroflexion associated with disease of the broad ligaments; 6 had pain referable to the whole pelvis; 6 had pain in the left side; 1 had pain in the hypogastrium; 3 had pain in the lumbar and sacral region; 7 had headaches.

In 26 cases of trouble with broad ligaments, in 1 pain was referred to both sides; 20, in left side; 5, right side; broad ligaments and anteflexion, 6 cases; broad ligaments and retroflexion, 16—total, 48. Among these are included those masses of inflammation in which are bound up the ovaries and the tubes in such a manner that it is difficult to differentiate them one from the other. It is interesting to note that in 12 cases out of the 26 of trouble in the broad ligaments that the disturbance extends beyond the pelvis, while in the complications with anteflexion and retroflexion, 24 in number, 8 only had trouble, and all of those referable to the head.

In considering the 16 cases of ovaritis, I am unable to make an exact statement with reference to prolapsus of the ovaries associated with ovaritis, but my impression is that the cases of prolapsus without ovaritis which come to the physician for aid are very few in number, and also that the cases of ovaritis without prolapsus are equally few. In 8 cases the pain was general, except in 1 instance, when in the left side; in 2 cases, in which both ovaries were prolapsed, both sides were affected; in the other cases, 3 of each, the pain was referred to the corresponding side; 2 had headaches, 1 of whom felt as if her head were on fire; 2 were dizzy, 2 had hysteria, 1 had attacks of fainting, 1 felt cold as ice on the left side.

In 4 cases of anteflexion with ovaritis 2 had general pain in pelvis; 1, pain in the left side; 1 had pain in the back, 1 had dyspepsia, 1, nausea—all four suffered from headaches; 2 had pain in the heart and 2 had general nervousness.

In 4 cases of retroflexion associated with ovaritis, 2 had general pelvic pain, 2 had pain in left side (corresponding to ovary) and the back. All were generally nervous, and had headaches. Summary: Ovaritis, 16 cases; ovaritis and retroflexion, 4 cases; ovaritis and anteflexion, 4 cases—total, 24 cases.

The reason I present so few cases of ovaritis complicated with displacements is not because they are lacking, but because they are more often complicated with other inflammatory conditions of the pelvis, such as cervicitis, endometritis, and parametritis. I think, however, that these cases are typical, and show that anteflexion, associated with ovarian disease, gives rise to a more general nervous disturbance than almost any other complication.

There are 26 cases of metritis, in which are included subinvolution and the more chronic hyperplastic conditions. Sixteen had general pelvic pain; in 1 the pain extended down the leg; in 2 the pain was in the right side, and in 2 in the left; 1, in the hypogastrium; 4, in the back. I find no disturbances of the alimentary canal recorded. Five had general headaches; 1 had frontal headache; 1, of the vertex; 3 had cold and chilly feelings. In 4 cases of anteflexion associated with metritis, the pain was located in the pelvis—1 in both sides and back, 1 in hypogastrium, and 2 in the back. Cases of metritis with retroflexion, without other complications, are not numerous on the list. Two cases, with decided pain in the back and general nervousness, are all that I can bring forward just now. It is true, I think, that a metritis uncomplicated with flexions gives rise to little disturbance or discomfort outside of the pelvis itself.

In 26 cases of subacute and chronic parametritis, 16 complained of pain in the whole pelvic region; 1, the pain extended down the leg; 3, it was on both sides; 1, in the left side; 5, in the back; 4 had dyspepsia; 1, nausea; 8, general headaches; 1, frontal headache; one felt prickling like needles, another was sleepless.

It must be remembered, with reference to these cases as well as the others, that I only bring out the distinctly local and reflex nervous symptoms.

I have endeavored, in considering the cases of the cervix, to eliminate all other pathological conditions. So much has been written about the reflex influence of cicatricial tissue remaining in cervical angles, that the matter has assumed surgical importance. The 14 cases of fissured cervix which I present were without inflammatory trouble, but the cases of cervicitis and endocervicitis were, many of them, complicated with lacerations. Of the fissured cervices, 5 had pain in the whole pelvis; 1, on the right side; 2, on both sides; 1, on the left; 2, in the hypogastrium; 4, in the back; 2 complain of flatulence; 1, of general headache; 1, of frontal headache; 1, of curious sensations about the umbilicus. Of the 47 cases of endocervicitis, 36 had general pelvic pain; 2 had pain in the right side, 1 in both sides, 1 in the left side, 2 in the hypogastrium, and 5 in the back; 5 complain of flatulence, 1 of nausea, 13 of general headache, 2 of headache of the vertex, 3 of dizziness; 1 was hysterical; 2 were sleepless; and 1 was drowsy.

Of the 61 cases of pathological conditions of the cervix, 22 had disturbances outside of the pelvis. The presence of headache was noticeable.

Of the 517 cases, 170, or about thirty-two per cent., have nervous troubles extending beyond the pelvic region. It is interesting to note that, in about half of the cases (226), the pain and discomfort were referable to the whole pelvis, and that pain in the left side is twice as frequent as in the right.

Second.—It has been shown that mere mechanical displacements give rise to almost no disturbance in complete prolapsus. In the other degrees of prolapsus the pain comes from the pulling and stretching of the tissues. Retroflexion occasions the most nervous disturbance outside of the pelvis.

Third.—It can be seen that the amount of disturbance is in every way proportioned to the amount of uterine tissue involved, and the length of time the disease has continued.

Fourth.—It is plainly shown that the reflex nervous symptoms are no more severe nor extensive that arise from displacements and inflammatory conditions of the uterus and its appendages than would be produced by pathological conditions of the same extent and the same chronic character in other parts of the body. When these are present a previous neuropathic tendency, either acquired or inherited, probably has existed, and the uterine trouble is generally extensive and of an aggravated nature, which, acting on the central nervous system, produces a display of disturbed innervation at the periphery or of disturbed cerebration, which results in neuralgias or hysterias.

Fifth.—In these studies the effects of uterine trouble upon the eyes have been carefully considered. Three cases, 2 of endometritis and 1 of inflammation of the broad ligaments, are found. I have met others, but in

TABLE OF 517 CASES SHOWING THE NERVOUS SYMPTOMS, LOCAL AND REFLEX, ARISING FROM DISPLACEMENTS AND INFLAMMATIONS OF THE UTERUS AND ITS APPENDAGES.

Grand total	517		226																			170

From an inspection of these cases, as well as looking through the very many others which were not sufficiently typical to come under classification, the following deductions have been made:

First.—Nervous disturbance outside of the pelvis is not nearly as frequent in disease of the uterus and its appendages as is generally believed. The impression that one severe case makes, effaces that of dozens of simpler ones. Moreover, gynecologists who are men are apt to meet only the severer cases, since women suffer long and in silence before undertaking a treatment which does such violence to their natural modesty. The eminent specialists who have done most of the writing on this subject encounter the most severe and difficult cases, and their object, often, in writing, is to present peculiar and extraordinary cases.

these, and looking over the literature, I have reached the conclusion that the eye-trouble is generally due to anæmia and general asthenia, and it is doubtful if it can be proven that such troubles with the eyes occur more often in uterine diseases than in others which would produce a similar state of anæmia and depression of the general bodily strength.

Sixth.—Many nervous symptoms are not present *because* of uterine disease, but are due to the constipation and anæmia with which it is so often accompanied.

Seventh.—Nervous disturbances outside of the pelvis are much more prevalent among the more highly organized women of the higher classes than among those of the lower, who have less time to think of themselves, and much less vivid imaginations.

Eighth.—The attention should be called to the fact that sacral neuralgia often simulates uterine disease; the pain is very like that described in many of the inflammatory conditions with displacement, and even with ovarian trouble. It is often associated with pain extending down the leg, and pain referred to the sides and the back, and it is also accompanied with general nervousness. I recall, now, three cases of sacral neuralgia in which the nerves were tender at their exit on the right side, and the great pain complained of was on the left side.

The minute anatomy of the nerves of the pelvis, and its relations with the so-called sympathetic, is far from precise, and we must turn, as has been done in the absorbing questions of brain-localization, to clinical data to substantiate hypothesis and theory. I am inclined to think that most of the reflex troubles leave the pelvis through the nerves connecting with the spinal cord, and are thence reflected to the brain, and from the brain to the periphery.

It is not my purpose to discuss at length the treatment, which might properly come within the limits of this paper, but only to speak of the remedies which, in these cases, have best served their end. If extensive relaxation of vaginal walls and uterine ligaments existed, astringents were used, of which iodine and tannin have proved the most successful. In using tampons for support, great care was taken to make them of such a size that they would support without distending the parts. In non-inflammatory conditions a well-adjusted pessary was the great desideratum. In a case of retroflexion associated with metritis, complete relief from the most distressing dyspeptic symptoms occurred in a few hours after the uterus was replaced and held in position by a pessary. In inflammatory conditions, belladonna, combined with iodine and glycerine, has proven the most useful in relieving pain and taking away the extreme sensitiveness. In the majority of cases the copious injections of hot water have been beneficial. I do not, however, believe in the present wholesale employment of this remedy. I have tried similar cases side by side, one using four quarts of hot water night and morning, and the other not. The curative results were obtained in about the same length of time. In cases of perimetric inflammations, acute and chronic, the hot injections are, indeed, beneficial in the vast majority of instances. In a few cases, for some unknown reason, they have been illy borne, and, instead of allaying the pain, they have increased it.

In all the long list of remedies addressed to the nervous system, there is none that can compare with the bromide of potassium. Five years ago I began to use it, having witnessed its almost marvellous effects in several cases in which I had tried it. Since then I have seen several articles in which it has been extolled. I always combine it with a bitter tonic. It certainly has a direct effect upon pelvic inflammation, aside from the soothing effect upon the nervous system. Where there is general nervousness, with a tendency to hysteria, a mixture composed of equal parts of valerian, aromatic spirits of ammonia, and compound spirits of lavender has been satisfactory. The ammonia renders the valerian less disagreeable. Next in the list stands a combination of hyoscyamus and camphor. The pill-form of these drugs commends itself, since it is more agreeable to the patient, but I have seldom been able to obtain anything like the results with pills. They probably do not dissolve. Galvanism has been very successful in allaying the pelvic and general pains.

"THE MADISON," 25 MADISON AVENUE.

ECCHONDROSES OF THE SEPTUM NARIUM AND THEIR REMOVAL.[1]

BY CARL SEILER, M.D.,
PHILADELPHIA, PA.

I FEEL a great hesitancy in bringing before you a paper on the subject of ecchondroses of the septum of the nose, because, after having read the admirable—one might almost call it classic—paper on deformities of the septum which was read before the Academy by my esteemed friend, Dr. Frank H. Bosworth, not much more than a year ago, little remains to be said that he has not pointed out. Yet, like him, I have been struck with the great importance of these excrescences of the septum in the production of the various, and often remote, symptoms which we notice in cases of chronic nasal catarrh; and for this reason I hope you will pardon me if I give you my personal experience and the result of my own observations, which extend over a period of several years. I will confine my remarks, however, to those excrescences which are found on the surface of the cartilaginous plate of the septum, and leave out of consideration those exostoses and deformities which are found on the vomer, or those which are in connection with deviation from the normal position of the septum. Long before I realized that these protuberances on the surface of the cartilaginous septum played an important rôle in the production of the symptoms of chronic nasal catarrh, I was aware of their presence, and devised a little instrument which would assist in the differential diagnosis between them and deviation of the septum, a description of which was published in the second edition of my Handbook. Since then I have more and more come to the conclusion that it is necessary in many cases to restore the normal smooth surface of the septum in order to cure the chronic nasal catarrh.

The origin and growth of these cartilaginous excrescences which are seen in a great many of the cases, some of which have come under my observation, puzzled me greatly—the more so as I cannot accept the theory expressed by many, and also by Dr. Bosworth, that they are of traumatic origin; and it was not until I had occasion to watch their formation in several instances that my opinion as to their origin was formed. And, therefore, I think that a short history of one or two instances will be of interest.

Mrs. T——, wife of a physician, consulted me at the request of her husband, three years ago, on account of a chronic nasal catarrh. An examination of the nasal cavities showed a perfectly formed normal septum, but a turgescence of the turbinated tissue over the anterior portion of the lower turbinated bone, which on the right side was in contact with the mucous membrane of the septum. As she declined positively any surgical interference or cauterization of the superabundant tissue, I gave her an alkaline spray to use at home, and did not see her again until a year later. She then told me that she was better, but that the obstruction in the right nostril had been permanent, the nasal cavity opening up only occasionally, and then allowing the passage of air but for a few moments. For some time she had noticed that her nose, which had formerly been straight, had a tendency to bend over to the left side. There was no history of any blow or fall on the nose. An examination gave an entirely different picture from that seen at the first examination, inasmuch as the cartilaginous septum was seen to bulge into the left nasal chamber, while on the right side there was a depression corresponding in size and position to the projection of tissue from the lower turbinated bone. This depression was bordered in front by a decided ridge, which ran obliquely upward. She again refused to be operated on, and I did not see her until a short time ago. An examination revealed the following condition: The tip of the nose was considerably deflected from the median line toward the left side; the left nasal chamber was partially obstructed by a decided bulging of the cartilaginous septum, on the surface of which a tit-like projection came in contact with the turbinated tissue of the lower turbinated bone. On the right side, the turgescence of the turbinated tissue was still present, but the depression which had existed at the former examination had disappeared, and in its place was seen a shelf-like projection from the surface of the cartilaginous plate of the septum running back to a considerable distance. The upper surface of this shelf was gently sloped downward, while the lower surface was slightly concave, and separated from the floor of the nasal chamber by a space of about one-eighth of an inch, so that a probe could easily be passed between it and the floor of the nose. The most prominent symptoms were fits of violent sneezing with every sudden change of surface temperature, such as getting out of bed, going out of a warm room into a cold one, or into the open air, and so forth; severe neuralgic headaches over the right temple, obstruction to nasal respiration, chronic laryngeal inflammation, and accumulation of thick viscid mucus in the naso-pharyngeal cavity, which had to be removed by hawking.

---

[1] Read before the Laryngological Section of the New York Academy of Medicine.

Another case in which I observed the development and growth of an ecchondrosis on the surface of the septum was that of a boy, about fourteen years of age, who was afflicted with a large papillomatous growth in the larynx, and whose nose I examined only incidentally. His nasal chambers were perfectly normal as far as the anatomical relation of the parts was concerned, but there was a somewhat deficient watery secretion, and a tendency toward the formation of scabs of dried mucus which adhered to the surface of the septum, particularly on the left side, and which he was in the habit of removing with his finger-nail. I cautioned him against this habit, which, as I explained to his parents, was likely to lead to a perforation of the septum. The papillomatous growth was successfully removed, and I did not see the patient again until about eighteen months later, when he returned with a chronic laryngitis which his parents thought was a return of the tumor, as it was accompanied by cough and hoarseness. He also complained of occlusion of the left nostril, which prevented free inspiration; but there was no obstacle to the outflow of the air, and his mother told me that he breathed heavily at night, and slept with his mouth open, expectorating in the morning large scabs of dried mucus. On inquiry, I found that he had persisted in picking off scabs with his finger, and that there were frequent slight nasal hemorrhages. I fully expected to find my prediction verified, viz., that he had scratched through the cartilaginous septum, thus producing a perforation. But such was not the case, for, instead of a perforation, I found on examination a conical projection from the surface of the septum on the left side, which was in contact with the atrophic turbinated tissue of the lower turbinated bone. Its apex was covered with dried mucus, and, on removal of which, presented a bleeding surface denuded of mucous membrane. The right side showed nothing abnormal except that the mucous membrane was dry, and the turbinated tissue slightly atrophied. The most minute interrogation of the patient and his parents failed to elicit an account of any injury to the nose by a blow or fall during the interval between the two examinations, and for a long period before I saw the boy.

In a number of other cases have I had the opportunity to observe a similar process of development of these ecchondroses of the cartilaginous septum, without the presence of a decided deviation existing previously, so that I have come to the conclusion that these simple cartilaginous excrescences are due, not to external traumatism, but to internal local irritation of the mucous membrane of the cartilaginous septum primarily, and of the perichondrium secondarily. If we consider that a turgescent or hypertrophied portion of the turbinated tissue, which for a considerable length of time is in contact with the mucous membrane of the septum, must necessarily exert a certain amount of pressure upon that mucous membrane and upon the perichondrium underlying it, and that even a very slight pressure, when it is kept up for a considerable period of time, will produce local congestion of the part pressed upon, be it on the outer integument of the body or the mucous membrane, it seems plausible to assume that this local congestion gives rise to changes of nutrition of the part sustaining the pressure. Taking into consideration the peculiar histological structure of cartilage, and particularly of hyaline cartilage, in which the blood is supplied by loops of vessels dipping into the substance of the cartilage from the perichondrium, and the nutrition of the cells is carried on by osmosis from one to the other without the intervention of a capillary net-work of blood-vessels, we can readily see that a localized increase of blood-supply to these loops must necessarily give rise to a *more* rapid cell-division and proliferation of the intervening cartilage-cells than is demanded to supply the waste by cell-death, and localized increase of cartilage-tissue must result therefrom.

In the majority of cases the cartilaginous projections from the surface of the septum corresponded in position and size to the line of pressure by turbinated tissue, and in those cases of atrophic rhinitis in which they are found, careful examination of the patient will elicit the fact that at some former period a hypertrophic rhinitis has existed, which has given rise to the ecchondroses in the manner described. It is, of course, impossible to state what length of time is required for their formation, and how long the pressure must exert its influence before any elevation on the surface of the septum becomes apparent. And, further, it is impossible to give any reason why, in some instances, no apparent redundancy of tissue results from long-continued pressure by the turgescent turbinated tissue. Individual peculiarities in this case, as in many other pathological formations in the body, must account for the differences noted in different cases.

In a short paper on this subject read before the German Medical Society of Philadelphia, last spring, I mentioned some instances in which an excessive growth of ecchondroses had caused a union between them and that portion of the turbinated bone lying opposite to them, so as to form a bridge across the floor of the nose, and explained this union by the fact that both the top of the ecchondrosis and that portion of the turbinated tissue which pressed against it had become denuded of mucous membrane, and an exostosis from the turbinated bone had projected to unite with the ecchondrosis on the septum. Since then I have had the opportunity to watch a case in which this condition existed, but union had not as yet taken place. In order to satisfy myself as to the result, I refrained from operating, and found that in the course of three months a firm union between the two had taken place, and the bridge was covered with mucous membrane, intact as far as I could determine, thus proving in this instance my surmise, as to the origin of these bridges, to be correct.

I will not tire you with an enumeration of the many and varied symptoms to which these obstructions to nasal respiration give rise, particularly as they have been so well described by Ingalls, Jarvis, Bosworth, Allen, John Mackenzie, Hinkel, and others, and will only mention one peculiarity, which I do not recollect to have seen a description of in any of the writings on this subject, viz., the valve-like action of the alæ of the nose when ecchondrosis on the septum exists low down. It will be noticed that in these cases inspiration alone is obstructed, because the pressure of the air upon the external surface of the ala of the nose, due to the suction, causes it to move slightly inward, and the lower portion of the turbinated tissue coming in contact with the ecchondrosis, more closely obstructs the lower orifice of the nasal chamber, like a valve which, as in the tube of an air-pump, permits the exit of the air, but prevents the influx through the same channel. By inserting a nasal speculum or dilator into the nostril this valve-action can be prevented, and the patient can breathe in and out with equal facility. A like result is obtained, if there is no other obstruction farther back in the nasal chamber, by removing a sufficient amount of the cartilaginous mass to prevent contact with the turbinated tissue during respiration.

I will also refrain from describing in detail the various shapes and positions of these cartilaginous excrescences, as this point has also been fully discussed by the above-mentioned writers, and will only add that my own experience has taught me that, if they have existed for some time, they are apt to become ossified or calcified in the centre. This ossification makes their removal much more difficult than it would otherwise be, and necessitates the employment of instruments which are capable of penetrating through this hard centre, so as to restore the normal flat surface of the septum.

Various writers have suggested and used a large variety of different instruments for these operations, such as the saw and knife, the plough, the gouge, the snare, the rotating-knife or burr in the surgical engine, and so forth; but a careful consideration of the requirements of individual cases will at once show that none of these instruments can be successfully used in all cases to the exclusion of the others, and the armamentarium of the operator should include them all.

But we must take into consideration that most operators have a particular fondness for this or that instrument, and prefer to operate with it rather than use any other, if this is possible; probably because they have acquired especial dexterity in its manipulation. It is, therefore, natural that they should praise their pet tool, and obtain results with it which others, with less dexterity in its use, can never hope to arrive at.

The object is to remove the redundancy of tissue as thoroughly and quickly as practicable, leaving a plain surface without ragged edges, and to perform the operation with as little pain and inconvenience to the patient as possible. And this can only be done by adapting the instruments to the requirements of the case.

Before I proceed with the operation, however, in a given case, I treat the nasal mucous membrane with a view to reduce the existing hyperæmia, for it is my experience that, if any surgical interference is undertaken at once, the shock following the operation is much more severe, and the wound does not heal as kindly nor as rapidly as when all acute or subacute inflammation has first been removed. For this purpose I use a spray of an alkaline solution, and make lócal applications with glycerole of iodine by means of a cotton carrier. Formerly I used the ordinary Dobell's solution for the spray, and also as a wash to be sniffed up the nose by the patient, morning and night, but within the last two years I employ instead a solution composed of the following ingredients:

Sodii bicarb	ʒ viij.
Sodii bibor	ʒ viij.
Sodii benzoate,	
Sodii salicylate ....āā	gr. xx.
Eucalyptol,	
Thymol.........................āā	gr. x.
Menthol........................	gr. v.
Ol. gaultheria.................	gtt. vj.
Glycerine	℥ viiiss.
Alcoholis......................	℥ ij.
Aquæ ....q. s.	16 pints.

This formula gives a solution which is sufficiently alkaline to dissolve the thickened secretion adhering to the nasal mucous membrane, and as it is of the proper density, it is bland and unirritating, leaving a pleasant feeling in the nose. At the same time it is antiseptic and acts as a deodorizer, being in this respect far superior to Dobell's solution or any other non-irritating deodorizer and antiseptic. As it is, however, inconvenient for many patients to have so large a quantity of solution on hand, one of our Philadelphia druggists made the solid ingredients into a compressed tablet, so that one, when dissolved in two ounces of water, will make a solution identical in its effects with the solution made after the above formula, and my patients prefer the tablets to the solution.

As soon as the inflammation has subsided sufficiently, I introduce a pledget of cotton, saturated with a four per cent. solution of cocaine, into the nasal cavity so as to cover the ecchondrosis completely, and leave it there for about ten minutes, when it is removed, and a fine cambric needle inserted for the purpose of ascertaining whether all sensibility has been destroyed, and also to determine whether any ossification has taken place in the substance of the excrescence.

FIG. 1.

If the ecchondrosis is in the shape of a conical projection or of a ridge running from below upward, and if no ossification has taken place, I prefer a small, double-edged knife, slightly curved on the flat (Fig. 1), with which I make an incision, first from below upward to about the middle of the excrescence, and then cut from above downward until the two cuts meet, and the cartilaginous projection is ablated. If there exists a hard centre which cannot be cut through with the knife, I carry the two cuts from below and above to this centre, and then use a flat chisel (Fig. 2) to cut through the bony portion, which is easily effected by tapping the handle slightly with a leaden mallet (Fig. 3).

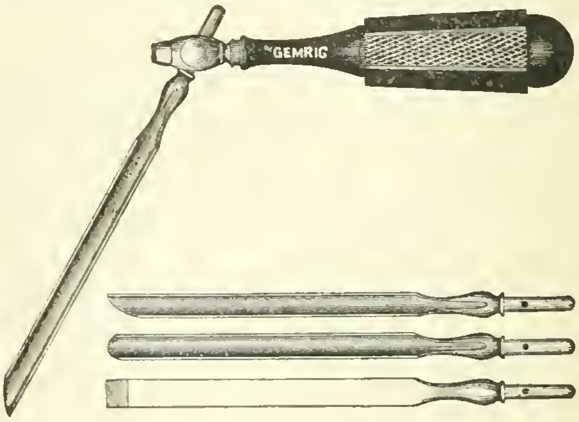

FIG. 2.

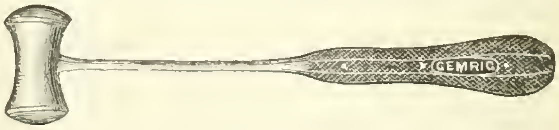

FIG. 3.

The two cuts are necessary because the knife, after having passed through the cartilaginous tissue, finds not sufficient resistance in the mucous membrane if the operation is made with one sweep of the knife from above downward, and the ablated piece falls over into the mass of coagulated blood, being still attached to the surface of the septum at its lower edge by the mucous membrane. It is then difficult to grasp with the forceps, and much time is lost in finally severing the mucous membrane.

If, on the other hand, the shape of the ecchondrosis is shelf-like, with a downward-sloping upper surface, and a concave under surface separated from the floor of the nose by a narrow space, and running backward for some distance, I know beforehand that I have to deal with an ossified excrescence, and proceed as follows: After having thoroughly anæsthetized the parts with cocaine solution, I introduce a grooved director, slightly bent at an angle, into the space between the floor of the nose and the under surface of the shelf-like projection, with the groove upward. I then dilate the nostril to its full extent with Bosworth's (Fig. 4) or Jarvis' self-retaining nasal dilator, and insert the dull point of a plough-shaped knife (Fig. 5) into the groove of the director, pushing it backward so as to cut through the base of the projection; very much in the same way as a wood-carver uses a similar tool. As soon as I find that the bony centre presents an obstacle to the further progress of the knife, I remove the latter and insert a gouge—the cutting edge of which is slanting—with its point into the groove of the director, and with a few blows from the mallet upon the end of the gouge, I cut through the ossified portion. In order that the view of the nasal cavity be not obstructed by the handle of the instrument and the hand holding it, I find it advantageous to insert the tool into the handle at an angle of about sixty degrees fastening its stem by a set-screw, and allowing the former to project slightly so as to receive the blows from the mallet in a direct line with the direction of the cut to be made. The hand holding the cutting instrument should be steadied against the chin of the patient, so as to prevent injury to the parts beyond the projection, which might easily result from the cutting edge or point of the instrument getting out of line and going beyond the posterior end of the projection, into the vault of the pharynx. A little practice soon enables the operator to feel when the gouge has cut through the hard tissue. The tool is then removed, and, keeping the grooved director in position, a pair of scissors bent at an angle is passed along its groove, so as to sever any portion of the mucous membrane at the upper surface of the shelf which may not have been cut by the plough or gouge. A straight chisel is not as advantageous as the gouge, because it cannot be so easily kept in the line in which the cut should be made; and, although the cut surface is slightly concave, I have in no case observed any retardation in the healing of the wound from this cause. In the case of a union between the turbinated exostosis and the ecchondrosis of the septum, I have found it best to divide the exostosis first, with a saw, close to the turbinated bone, and then to ablate the ecchondrosis with the knife and chisel, or gouge.

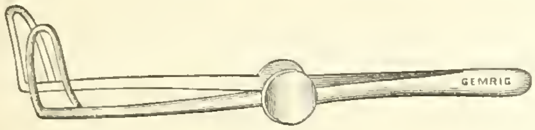

FIG. 4.

FIG. 5.

These operations are absolutely painless if the cocaine has fully anæsthetized the parts, and the only objection made by the patients is the jarring produced by the blows of the mallet upon the end of the gouge or chisel. The hemorrhage resulting from these cutting operations, as a rule, is comparatively slight, and can always be controlled by placing a pledget of borated cotton against the wound for a few hours. As soon as all oozing has stopped, this should be removed and the nasal cavity should be washed out twice daily with the antiseptic solution, so as to prevent any sepsis. The healing process is usually complete in about ten days, but may, in some cases, be prolonged for a few days more. There is no soreness of the nose, and no great amount of inflammation of the surrounding mucous membrane following the operation, and the patient is able to attend to his duties at once. I do not, however, wish to be understood that other methods of operation are not as successful, and that the saw or revolving-knife should not be used in cases of ecchondrosis of the septum. I only wished to give my personal experience, which, probably owing to want of dexterity with these instruments, has taught me that I obtain better results, and more easily, with the knife and gouge, than with the revolving-knife or saw.

1346 SPRUCE STREET.

A METHOD OF PROPHYLAXIS IN DIPHTHERIA.[1]

By AUGUSTUS CAILLÉ, M.D.,

VISITING PHYSICIAN TO THE GERMAN HOSPITAL AND TO THE GERMAN DISPENSARY (CLASS OF CHILDREN'S DISEASES), NEW YORK.

EVERY experienced practitioner has probably observed that in certain families one or more of the members regularly take sick with diphtheria in the spring or fall of the year.

This is particularly true in the case of children, and, according to my personal experience, the months of October, November, March, and April are those in which such patients are prone to contract the disease.

It occurred to me that persons thus frequently afflicted might harbor the diphtheritic poison, or the microbes essential to its formation and septic power, in their nasal and oral cavities most of the time, without damage to the organism; but as soon as active hyperæmia of a neighboring mucous membrane took place from any cause whatsoever, the germs of diphtheria would readily find foothold in this damaged mucous lining, and manifest their presence in the various ways and forms familiar to us.

In a spirit of investigation, and with the object of testing to a certain extent the correctness or fallacy of this view of auto-infection—which, by the way, may be held by other observers, and which is certainly not incompatible with our present knowledge of the disease under consideration—I selected eight patients of various ages, all of whom had suffered from true diphtheria, to my knowledge, twice or more prior to October 1, 1885.

Case.	Name.	Age. Years.	
1.	S. K.	14	Members of one family who have had diphtheria once or twice each year from 1882 to 1885.
2.	E. K.	16	
3.	L. K.	26	
4.	G. S.	3	Two attacks of diphtheria prior to October 1, 1885.
5.	E. B.	5	Three attacks of diphtheria prior to October 1, 1885.
6.	K. I.	12	More than three attacks prior to October 1, 1885.
7.	M. S.	3	Children belonging to one family; both have had diphtheria several times.
8.	G. S.	6	

The families represented in the above table by one or more members have been known to me for a long time, they live in different parts of the Tenth and Seventeenth Wards of this city, and each respective family has occupied the same house or apartments, and lived in the same surroundings, for a number of years. The adults enumerated above, and the parents of the children mentioned in my list, were intelligent enough to appreciate the importance of carrying out the following suggestions, viz.:

I. All carious teeth to be filled or extracted, and the teeth to be examined by a dentist from time to time.

II. The mouth to be thoroughly rinsed three times a day, after each meal, with one of the following solutions:

(*a*) Three per cent. solution of potassium chlorate in water; or (*b*) liquor sodæ chlorinat. in water, 1 to 20; (*c*) a saturated solution of boric acid in water (four per cent.); the liquids to be alternately used and changed every four weeks. They were to be used as a gargle, as a mouth wash, and dropped into the nostrils by means of a medicine dropper three times a day.

---

[1] Read before the New York Academy of Medicine, January 19, 1888.

III. In the case of the children not able to gargle, the liquid was to be dropped into each nostril from a pipette (medicine dropper), three times daily.

IV. These precautionary measures to be strictly carried out from October 1, 1885, for one year, or eventually two years, except during the hot months, in which diphtheria had never been observed in these families, and when most of the parties under observation were out of town.

In addition to these eight cases, two infants, each about one year of age, who had never been sick with diphtheria, were treated during the time stated above in the following manner: Ten to fifteen drops of the boric-acid solution was dropped by means of a medicine dropper into each nostril twice a day, immediately on awaking and before sleeping, with the understanding that the boric acid solution was to be used in this way every three hours, if at any time symptoms of nasal catarrh should be noticed.

Results.—From October 1, 1885, to December 1, 1887, not one of the persons experimented upon suffered from diphtheria.

Patients Nos. 1, 3, 4, 6, and 8, had several attacks of acute pharyngitis and amygdalitis during the time of experimentation, characterized by a dusky redness of the throat with moderate swelling of the tonsils, and a moderate rise of temperature.

An adult member of the family at the head of the list (but not under observation) suffered from diphtheria in February, 1887. Patients 1, 2, and 3, members of the same family, were exposed to infection, but did not contract the disease.

The mother of one of the infants took sick with diphtheria in March, 1887; also the servant in the family. The infant was isolated from the sick ones, but not removed from the house, and did not take sick.

Remarks.—This brief but accurate report of the above facts does not embody the absolute proof of prophylactic cause and effect, but it certainly goes far to establish the belief that, if the nasal and oral cavities are kept tolerably clean by means of harmless, non-irritating liquids known to possess antiseptic (disinfectant) properties, the frequency of diphtheritic infection is markedly reduced.

The treatment of diphtheria is a perennial subject for discussion all over the civilized world; at the same time, rational and thorough prophylaxis has not received the attention from practitioners in medicine which it merits.

If we scrutinize the vast amount of information which has accumulated concerning the manifestations of what is known to us under the name of diphtheria—information which has been furnished by careful and competent observers, and by some of the most acute minds of the present century, in the domain of practical and experimental medicine—we must candidly admit that we are not in possession of positive knowledge as to the nature of the diphtheritic virus, its mode of propagation, and its predilection for certain individuals, notwithstanding the most painstaking research of Loeffler, Emmerich, Wood, Formad, and others.

If we admit our ignorance of the true nature and significance of so-called diphtheria, we must also admit that we cannot with certainty differentiate clinically between contagious and non-contagious acute inflammatory changes of the mucous membrane of the naso-pharynx and buccal cavity; and we are thus compelled to look with suspicion upon all such changes, and apply our prophylactic and therapeutic measures in accordance with this view, which was first publicly proclaimed by A. Jacobi twenty-eight years ago, in a paper (published in the New York *Medical Times*) on diphtheria and diphtheritic affections, and publicly upheld in his controversy with B. Fraenkel, of Berlin (*vide Berliner Klin. Wochenschrift*, Nos. 17 and 18, 1886), in an article entitled "Follicular Amygdalitis," published in The Medical Record, November 27, 1886.

Furthermore, we may safely commit ourselves to state that, although the line of treatment which we pursue in diphtheria is not without its influence in checking the progress of the disease and in stimulating the system until the disease shall have exhausted its virulent properties, we have no means of absolute control at our command, or, in other words, no specific treatment for diphtheria.

And, finally, as a logical sequence of such reasoning from facts, we certainly do not assert too much if we declare that, in the present state of our knowledge, practical methods of prophylaxis in diphtheria will be of more value to the community than the most approved method of treatment, whatever that may be.

And now, a few words about prophylactic measures. We have, in the first place, general preventive measures, such as hygienic legislation, enforcement of sanitary rules regarding dwellings, ventilation, food, occupation, erection of isolation hospitals, general disinfection, etc.; and, in the second place, methods of prophylaxis within the family and directed to or against the person or individual.

Without intending to underrate the importance of general sanitary enactments, I would suggest that in a large city only a limited number of inhabitants can live in salubrious surroundings, and that the majority of the people in large cities are not, and never will be, able to live in first-class healthy abodes; the more so as we are still in the dark as to the actual source of danger from infectious diseases, which makes it all the more difficult to escape from their embrace.

I am of opinion, therefore, that while the dictates of sanitary science should be carried out strenuously, the utmost importance should be attached to personal and individual preventive measures.

Now let us take up for one moment the subject of individual prophylaxis, and abstract from the vast literature of diphtheria such prophylactic suggestions as appear simple and practical. It has been a surprise to me to find the subject barely mentioned in the majority of our text-books and works of reference.

In the latest edition of Ziemssen, in Oertel's article on diphtheria, no mention is made of prophylaxis, and we look in vain for information on the subject in such text-books as Eustace Smith, "Diseases in Children," 1884; West, "Diseases of Infancy and Childhood," 1874; Day, "Diseases of Children," 1881; Meigs and Pepper; Rilliet and Barthez, "Maladies des Enfants," Paris, 1887; or the latest edition of Vogel's "Children's Diseases," who simply mentions isolation and fumigation of infected localities. Preventive methods are not mentioned in Buck's "Reference Handbook of the Medical Sciences," New York, 1886; and the author of the article on diphtheria, in the latest edition of "Eulenburg's Cyclopædia," disposes of the subject in ten lines, stating that he has seen no advantage from prophylactic gargles, and is of opinion that strong solutions do harm by causing hyperæmia, which is undoubtedly true. He mentions potassium permanganate, vinegar, alcohol, lime-water, carbolic acid water one-half per cent., and chlorate of potassium solutions as liable to do harm.

Austin Flint, in his "Principles and Practice of Medicine," speaks only of isolation of patients, and thorough disinfection of dejections and all articles which have been in contact with patients.

E. Schottin, "Die Diphtheritische Allgemein Erkrankung," Dresden, 1885, says, page 83: "I have known all attempts to prevent the spread of diphtheria by prophylactic measures to fail."

Semple, in a monograph on diphtheria, 1879, and E. S. Gaillard, "Diphtheria," a prize essay (Richmond, 1867), do not mention preventive measures; and G. F. Wachsmuth, "Die Diphtheritis Heilmethode," Berlin, 1886, simply says that a sponge-bath with friction is good preventive treatment for children.

In some other publications I have found the subject at least under brief consideration.

Max Gaube ("Entstechung der menschlichen Rachendiphtherie," Leipzig, 1884), says: "A healthy mucous membrane of the pharynx and nose is an impediment to diphtheritic invasion."

Rigauer ("Die Diphtherie u. das kalte Nasenbad," Leipzig): "The abundant mucus in the naso-pharyngeal catarrh of children is excellent material for the growth and development of diphtheritic virus, which gets into the system through some epithelial lesion."

F. Stecher, a practitioner in Munich, has written an excellent monograph ("Zum Schutz wider die Diphtherie," Berlin, 1884), in which he says: "A healthy condition of the throat has the same importance in relation to diphtheria as a healthy stomach in times of cholera." He advises isolation, disinfection, and the wearing of a mask filled with salicylated cotton. Dust and smoke are to be avoided, carpets are condemned, children's necks should be washed daily with cold water, and they should gargle as soon as the throat is unusually red.

C. Gerhard ("Verhandlungen des 2. Congresses für innere Medizin") says: "I feel convinced that prophylaxis in the household, and frequent cleansing of the nose and throat for the purpose of keeping them in a healthy condition, will do more good than the most approved methods of treatment."

In our own country, J. L. Smith ("Diseases of Children") has a short chapter on preventive measures in diphtheria. He advises isolation, disinfection of apartments, linen, spittoons. When diphtheria is prevalent children's fauces should be frequently and carefully inspected, and if they seem too red they should be sprayed with proper remedies.

H. Francotte ("La Diphthérie," page 398, Paris, 1885) says: "At the present time there is no efficacious prophylactic treatment for diphtheria. Children should be accustomed to changes of temperature by cold frictions of the whole body, frequent gargling with cold water, and an abundance of fresh air; and he suggests that gargles with antiseptic liquids may do some good by carrying away putrescible matter from the oral cavity. He also reports that Marotti, of Venice (*Gazz. Med. di Venezia*, October, 1884), has made twenty preventive inoculations for diphtheria in 1864.

Vincenzo Cozzolino ("Tratato della Difteria," Naples, 1887) reports, on page 309, that: "Norberto Perotti (*Archivia di Pathologia Infantile*, March, 1885) recommends the black sulphide of mercury mixed with equal parts of gum arabic, to be insufflated. He claims that persons treated in this manner escaped contagion during an epidemic of diphtheria in Albano Leziale, a town in which he practised, except two children in his own family. Cozzolino believes that it may be possible in the future to prevent diphtheria by inoculating the attenuated virus.

I do not know how I could aid the cause of preventive measures in diphtheria more than by quoting the language of a physician who has studied this disease the greater part of his life.

Abraham Jacobi, in his treatise on diphtheria (the last edition of which appeared in 1880), says, on page 32: "As there are individuals, so there are families which have a predisposition to disease, and there are others in whom, notwithstanding ample exposure, infection does not easily take place."

"That the contagiousness of diphtheria should still be doubted is hardly possible, and still the public act as if it did not exist. It is certainly transmitted by spoons, glasses, handkerchiefs, and towels. Oertel has seen diphtheria of the pharynx which was communicated by the act of kissing, and developed in two days."—Pages 57, 58. "One important axiom must be borne in mind, namely, that prevention is more easy than cure, and there are certain prophylactic measures which will prove valuable in the hands of every good physician. It is necessary, under all circumstances, that the mouth and pharynx of every child be constantly kept in a healthy condition."—Page 158.

Cases of pharyngitis and amygdalitis, no matter whether influenced by an epidemic or not, furnish an indication for the prophylactic use of potassium chloride.

On page 172 of the same work we read: "Unnecessary petting of the patient on the part of the well ought to be avoided—kissing forbidden. The well, or apparently well, children of a family that have diphtheria at home must not go to school or to church. Teachers ought to be taught to examine throats, and directed to examine every child's throat in the morning, and return home every one barely suspicious."

Finally, I would refer to Dr. A. Jacobi's article on "Diphtheria Spread by Adults" (New York *Medical Journal*, September 24, 1884), and quote from his article on "Follicular Amygdalitis" (THE MEDICAL RECORD, November 27, 1886) as follows: "I claim that the name of follicular or lacunar amygdalitis is but a subterfuge for the lack of a correct or complete diagnosis," and "whether membrane or point, the contagiousness of the disease is the very same." With punctate diphtheria "the adult is in the street, in business, in the school-room, in the railroad car, in the kitchen and nursery. With this variety parents, while complaining of slight throat trouble, which is not heeded, kiss their children."

Can it be difficult to understand, in the light of such evidence, that the physician, if he be true to his calling, must strive henceforth to cultivate and carry out practical methods of prophylaxis in contagious disease? I think not.

Permit me to close this paper with a brief *résumé* of some of the points which appear to me worthy of attention.

In a city with densely populated districts, such as the Tenth, Eleventh, Fourteenth, and Seventeenth Wards of New York, the reconstruction of plumbing arrangements and erection of air-shafts in tenement-houses, are useful measures of sanitary reform if supplemented by universal attention to the details of individual disease prophylaxis, and it is the noble privilege of each member of our profession to aid our local health authorities by instructing the people in such matters as often as opportunity presents.

The overheating of school-rooms and living-apartments should be most emphatically denounced as dangerous.

Isolation of the sick should be explained and insisted upon, and the management of isolation hospitals for the poor should be such as to rapidly gain their confidence.

Enlarged tonsils should be reduced by the knife, or, better still, by means of the galvano-cautery. Carious temporary teeth of children should be removed promptly, and to the poor should be given the opportunity to have carious teeth filled with amalgam or cement for a nominal small fee or free of charge.

Parents should inspect their children's mouths and throats each day before sending them to school. Children readily learn to use their own fingers as tongue depressors, and it is important that they learn to gargle at an early age.

Children suffering from simple sore throat (apparently) should not attend school until they are quite well; and in follicular amygdalitis and other forms of acute sore throat, preventive measures should be strictly carried out.

Adults with sore throats should not mingle with children.

The kissing of children upon the lips should be forbidden, and parents themselves should set an example in this direction.

Children old enough to gargle and rinse their mouths should be taught to do so after each meal, a weak solution of one of the harmless antiseptic chemicals to be used; and in the case of young children such solutions should be dropped into the nostrils regularly twice a day, or oftener if symptoms of nasal catarrh supervene. The outfit necessary for carrying out such proper measures consists of one ounce of the antiseptic chemical, dissolved in a wine-bottle of water, and a medicine-dropper.

Recognizing that it is impossible to lay bare and control all sources of diphtheritic infection, it will be more practical to teach the individual to protect himself and his surroundings by striving to keep in a healthy condition those parts which are found by experience to be generally affected.

Necessity being the mother ot invention, let us hope and believe that in the near future we may have at our command simple methods of prophylaxis which may be safely placed in the hands of all rich or poor who are willing and intelligent enough to appreciate the benefit to be derived from their employment.

ON SOME POINTS IN THE MANAGEMENT OF THE EUSTACHIAN TUBE IN CERTAIN EAR AFFECTIONS.[1]

By OREN D. POMEROY, M.D.,

SURGEON TO THE MANHATTAN EYE AND EAR HOSPITAL ; PROFESSOR OF OTOLOGY, NEW YORK POLYCLINIC, ETC.

In the following observations no effort has been made to present the literature of this subject, but to present the writer's views and personal experience thereon.

Whatever may be faulty in these, it is hoped that the ensuing discussion may, as far as possible, correct. Many considerations must, from the nature of things, be presented from theoretical points of view, as actual demonstrations are often impossible.

In acute purulent inflammation of the tympanum it may not be proper to inflate while the inflammation is at its height, for fear of adding to the already augmented intratympanal pressure, and thereby increasing the pain. On the other hand, there may be great and instantaneous relief to pain by inflation ; besides this, inflammatory products are often removed per Eustachian tube, if not too tenacious in consistency. It is safe enough to at least gently try inflation and watch the effect. Politzer's plan is probably better in this connection than other methods.

In acute catarrh of the tympanum the obstruction of the Eustachian tube often is a factor in the production of pain in this wise : There is a tendency to vacuum in the tympanum, which adds to the pressure exerted by the drum-membrane and ossicula upon the supersensitive tympanum in a state of inflammation. This, I think, accounts for a certain relief to pain which often occurs during an attack of otitis in consequence of air passing into the tympanum, and which is accompanied by a prolonged crackling, snapping, or hissing sound, noticed by the patient. This in itself may cause an exquisite lancinating pain, but is quite momentary, and is often followed by the most grateful relief. It does not, however, follow that an aching ear should always be inflated, for in the earlier stages of the trouble, when the parts are tense with overfilled blood-vessels, this plan of treatment would be quite contra-indicated, as still further adding to the existing intratympanal pressure.

In certain cases where the hearing is considerably improved by inflation, but after deglutition immediately returns to its former state, it would seem that the tube itself was not altogether at fault, or perhaps not at fault at all. This point was discussed in my article on "Multiple Paracentesis of the Drum-membrane," published in the New York *Medical Journal*, in February, 1887, in which the ground was taken that the fault was not to any considerable degree due to the condition of the Eustachian tube, but to the drum-membrane. The latter was declared to be so stretched by the prolonged condition of collapse, as to have its superficial area considerably increased, rendering the condition of collapse one of preference, and that a restoration to a normal position was only accomplished by excessive intratympanal air-pressure, resulting from inflation. Naturally, the act of deglutition, opening the tube, would allow this excess of air to escape, and the return of the membrane to its former position would be a necessary consequence. The paracentesis, it may perhaps be remembered, was done with a view to diminish this redundancy of drum-membrane, so that a less sunken condition would inevitably result. A few of my paracentesis cases certainly favored this mode of explaining the phenomenon and the procedure seems a justifiable one. The different modes of rarefying the air in the meatus, used by many surgeons, point to the fulfilling of a similar indication.

I have noticed, as also have other aural surgeons, that, on inflating the tympanum, the hearing at first would reach a maximum point, then, on still further inflating, the hearing would become lowered, and, on causing the patient to swallow, the tympanum would not empty itself of the excess of air, even when the nostrils were compressed (which produces a partial vacuum in the upper pharyngeal space, thus aiding in the evacuation of the tympanum), and that no effect on the hearing was thus produced. I have ascribed this to the faulty action of the tubal muscles. This is more often seen in acute cases of catarrhal obstruction, and in these cases may be due more to the excessive swelling of the tube, which would render even a normal exhibition of muscular action inoperative in regulating its calibre, rather than faulty muscular action alone. This experiment may be a good one to test the power of the muscles of the tube.

There is still another fact regarding the muscularity of the tubes which is interesting, to wit : In a given case of one sound ear, with its fellow affected with a chronic aural catarrh, with its tube easily "forced" by Valsalva's inflation, that, on swallowing, the catarrhal ear shows interchange of air between the throat and tympanum, while there may be none of this in the perfect ear. Confining the nostrils during this experiment may simply exaggerate the phenomenon. It is a curious fact that in a normal ear the act of deglutition may sometimes empty the tympanum, and again act as an inflator. This array of facts readily suggests the possible value of frequent acts of deglutition as a means of gymnastics to the muscles of the Eustachian tubes.

In one case of mild acute catarrh of the Eustachian tube, of a few days' duration, it was noticed that air passed much too readily into the middle ear, occasioning a very disagreeable crackling, which was very frequent and annoying. There was a great amount of thin mucous secretion from the upper pharynx, and the region of the Eustachian tube was pale and seemed much relaxed.

A twenty-grain spray of nitrate of silver against the orifice of the tube relieved this symptom in fifteen minutes.

This symptom has been a difficult one to explain, but the result of treatment in this instance seems to indicate that there was lack of coaptation of the somewhat valvular-shaped faucial orifice of the tube, due to relaxation of the tissue, which was corrected by the nitrate of silver. One or two applications subsequently relieved the symptom completely, though I admit that, in cases of long duration, relief so prompt is not to be expected.

Another class of cases gives us a great deal of trouble.

Some time since I was asked by a practitioner about one of his ear patients ; it was a case of chronic aural catarrh, in which excellent hearing resulted after inflation, but after a few days the improvement failed to continue. I found he had duly treated the catarrhal condition and used the means ordinarily depended upon to relieve, and I was compelled to tell him that I could not offer any help. Unfortunately this is a condition seen in a considerable number of cases of chronic aural catarrh. Occasionally electricity seems to do good in this, possibly atonic, condition of the tubes.

The following case will illustrate the conduct of the Eustachian tube in recovery from acute purulent inflammation of the middle ear. The patient made a good recovery from the middle-ear trouble, with almost perfect voice, hearing, and about 12″ for the watch. He noticed that the Eustachian tube was easily "forced," that is, whenever he sneezed, blew his nose, swallowed, etc., that the air passed into the ear. At this time the hearing was slightly augmented by inflation. Treatment of the faucial extremity of the tube was continued for a few weeks with no striking result. Two months subsequently the watch-hearing had arisen to 16″, and on inflation it was 24″. He still had symptoms of the tube being easily forced, as before. I continued applications to the Eustachian tube, by means of my hard-rubber spray instrument, of carbolic acid, nitrate of silver, etc., with directions for the patient to practise swallowing many times a day, with the hope that the muscularity of the tube, by this species of gymnastics, would be improved. Subsequently the patient's hearing became nearly normal. This idea may have been suggested from Professor von Tröltsch's practice of using gargles with a similar end in view.

---

[1] Read before the Ophthalmic and Aural Section of the New York Academy of Medicine, December 19, 1887.

In this case there was very little pharyngeal trouble, and the conclusion was that the severe tympanal inflammation had more to do with disturbing the functions of the Eustachian tube than the pharyngeal trouble.

It has long been a prevailing opinion among the profession that the deafness, or the increased hardness of hearing, noticed in damp or stormy weather, was due in some way to the moisture in the atmosphere, or possibly to the augmented catarrhal irritation incident to inclement weather. The true explanation of this phenomenon, or a part of it at least, seems to be the diminished barometric pressure, which permits the tissues of the body generally to swell. This condition, applied to the walls of the Eustachian tubes, naturally would result in swelling, diminished calibre, and insufficient tympanal ventilation. It cannot be denied, however, that a catarrh often behaves worse in inclement weather.

In obstruction of the nostrils from polypi, adenoid growths, hypertrophic swellings of the turbinated bones, deviation of the septum, or the "stuffing" of the nostrils from an acute rhinitis or hay fever, the Eustachian tubes must suffer. Constant, or very frequent, interchange of air between the pharynx and tympanum, especially if accomplished with some violence, is fraught with great evil to the organ of hearing. The most violent otitis media may be caused by the rapid breathing of pneumonia, especially if the nostrils are, as is often the case, obstructed. In the latter condition, on the inspiratory effort, the air is more or less rarefied in the upper pharynx, and the tympanum is partially emptied of its air to equalize the air-pressure, while in expiration the opposite condition obtains, and air is forced into the tympanum, as the narrowed nostrils fail to carry off the great volume of air rushing from the lungs; the consequence will then be a to-and-fro movement of the air from tympanum to pharynx. Besides the inflammatory trouble excited by this manœuvre, we have the flapping, to-and-fro movement of the drum-membrane, which puts it on the stretch, and may ultimately spoil its elasticity. The foot-plate of the stirrup also must move in its oval window, somewhat like the piston of a pump, with considerable violence, and inflict not a little traumatism to these parts. Whether a moderate swelling of the mucous membrane covering the turbinated bones acts with special prejudice on the hearing, beyond the catarrhal aggravation it may engender, and associated with perfectly free nostrils, I am unable to say. I remember a patient with chronic aural catarrh who came under my care. His hearing was considerably lowered, but on inflation came up to nearly normal. He left my care without undergoing treatment, and was treated by an aural surgeon of recognized ability, who at once removed pieces of swollen mucous membrane from the turbinated bones, although the nostrils were as free as nostrils in general. I did not quite see the indication for doing this. but perhaps the doctor was right and I wrong. It may be needless to remark, in this connection, that we are at present passing through a somewhat violent period of heroic surgical interference with the nasal passages, and it is to be hoped that such interfering hands will learn to be more kindly disposed toward the upper air-passages in future. Another important indication for instituting a free passage through the nostrils is to prevent mouth-breathing. I will not here enter into the numerous indications for avoiding the latter, but simply content myself in remarking that in pure mouth-breathing the upper pharynx is no longer emptied of its secretion, and this retention aggravates catarrhal conditions of the Eustachian tubes. Besides this, it would seem that to produce the frequent necessary interchanges of air between the throat and tympanum, a column of air needs to be passing to and fro across the orifice of the Eustachian tube; that is, whenever the tubes open, air moving across its orifice is more likely to enter the tympanum than where the air is stagnant or not in motion.

Adenoid growths in the vault of the pharynx often disturb the functions of the Eustachian tube. The average American aural surgeon may be inclined to think comparatively light of these growths as obstructers of the Eustachian tubes and sources of irritation to a post-naso-pharyngeal catarrh. All are agreed, however, that when the growths obstruct nasal respiration they should be removed. In this country I believe that these cases are much less serious than in Europe. Within a few days, a former pupil of mine, just returned from London, describes cases of adenoid growths seen there, and which are frequent, where nasal respiration is almost, or quite, impeded, where the upper pharynx is filled with a soft mass resembling angle-worms to the sense of touch, bleed easily, completely obstruct the Eustachian tubes, and which may often be removed by scraping with the finger-nail. Great and permanent improvement to the hearing generally resulted from their removal. Little chance of return seemed to be the doctor's experience.

In enlarged tonsils there does not seem to be any direct mechanical obstruction of the Eustachian tubes; for, however great the increase in size may be, it is not in the direction to encroach upon the tubes. In enlarged tonsils there is great increase in secretion, the throat is cleaned oftener than would otherwise be necessary, and the general catarrhal condition of the pharynx is thereby much aggravated. This, of course, would act unfavorably upon the calibre of the Eustachian tube.

Perhaps a more important condition, however, incident to the enlarged tonsils, is the obstruction to both mouth and nose breathing. In any considerable enlargement of the tonsils it is manifest that mouth-breathing is interfered with.

It is also often true that nasal respiration will be rendered more difficult, as the tonsils, by their extension backward, will diminish the depth of the pharynx, through which nasal respiration must proceed, and result in interference. The influence of impeded nasal respiration on the Eustachian tubes has already been considered.

In tinnitus aurium we have, perhaps, one of the most urgent indications for treating the Eustachian tube that exists. Whatever the multiform causations of tinnitus may be, there is, certainly, one which often enough can be demonstrated to be the actual cause: namely, pressure on labyrinth waters from sunken drum-membrane, the consequence of defective ventilation of the ear-cavity. The demonstration, of course, consists in relief to tinnitus following the inflation.

If the neurologists oftener made an observation as to the previous nature of the Eustachian tubes, it is possible that less stress would be placed on certain symptoms pointing to brain diseases, such as vertigo, nausea, tinnitus aurium, incapacity to mental exertion, etc., which may, each or all, be only indications of pressure on the acusticus, due to obstructed Eustachian tube and sunken drum-membrane.

In otitis from acquired syphilis there is obstruction of the Eustachian tube quite frequently, in my experience. In many cases of specific otitis there seems to be present all the characteristics of ordinary otitis, with a strong tendency toward tissue-proliferation, especially about the foot-plate of the stapes, resulting often in enfeebled bone-conduction. I believe that I treat the Eustachian tube in these cases with almost as great frequency as in ordinary otitis. The hearing is very frequently improved by inflation in these cases, and I infer that I am right in treating the Eustachian tubes. Observe the frequency with which the syphilographer gives local treatment to specific sore throat.

My impression is that in otitis from hereditary syphilis the Eustachian tube is not often in a condition to require treatment, although the reverse of this sometimes obtains. It is manifest that when a syphilitic subject has a corroding ulcer near the Eustachian tube that appropriate constitutional as well as local treatment must be instituted to diminish the size of the cicatrix, which might close the orifice of the tube, from which recovery would be doubtful.

I always have had a strong prejudice against injecting fluids far up into the Eustachian tube, and especially into the tympanic cavity, in chronic aural catarrh. It has been done in this country, and especially by Professor Jones, of Chicago. It is again being done on the Continent, on the other side. Lately, Dr. Hepburn, of the Manhattan Eye and Ear Hospital, has done it, with the result of making the tube more pervious, but he at the same time punctures the membrane, so as to allow the fluid to escape through the perforation. This appears to the writer to be a rational procedure.

In deafness dependent on the administration of quinine there is naturally hyperæmia of the whole organ of hearing, more or less; but I have frequently noticed, especially where the quinine influence was not profound, that obstruction of the Eustachian tube from hyperæmic swelling of its walls seemed to be the principal lesion. The evidence of this appeared from the fact that inflation sufficed to relieve most if not all the symptoms, such as deafness, tinnitus, and unnatural voice-resonance. In obstructions of this kind it would be a very agreeable practice to spray a little two per cent. solution of cocaine upon the orifices of the Eustachian tubes, the effect on the hyperæmic swelling of the parts being almost instantaneous, and the patient is likely to experience the most delightful relief, though it may be somewhat temporary. Where the orifices of the tubes are pale, somewhat œdematous, and possibly relaxed, the cocaine seems to work well. I do not, however, believe that cocaine has so far proved to be more than a temporary means of relief. In one case, of an elderly lady about sixty-five years of age, I noticed a sound, also audible to the patient, much like the peeping of a chicken, which could be easily heard eight inches from the ear. It was rhythmical and constant; it had continued without intermission for several months, and I did not hear of its cessation previous to the patient's death, which occurred two years after this observation. I inferred that there was spasmodic contraction of the tubal muscles, causing the walls of the tube to flap against each other. I also infer that a senile tubal catarrh acted as an exciting cause, and that possibly electricity would have benefited the patient. I could not, however, treat her, as she lived remotely from town. Cases somewhat resembling this have been reported by others, and a similar explanation has been given.

As to the best mode of inflating the tympanum. On the whole, I believe Politzer's to be the most satisfactory; it is not attended by violence, the tube is not "forced," the faucial orifice is not molested by appliances for inflating, and there is less danger of inflating too frequently than by other methods (as it cannot be done without trouble). The modifications of Politzer's method I use frequently, as it takes less time, but I believe they are not quite equal to the genuine Politzer. Some have argued that in catheterization the beak of the catheter, coming in contact with the mouth of the tube, provokes a degree of irritation to the part, which acts curatively upon the catarrh. It is certain that the increased flow of mucus consequent on the application of the catheter to the mouth of the tube does temporarily relieve the turgid lining membrane and increases the calibre of the tube. In a general way I have always avoided traumatism in the treatment of catarrhal tubes as much as possible. The modern treatment of catarrh of the tear-duct is a good illustration of this principle—too frequent probing is avoided, and the probe is not left in as long as formerly; means taken to reduce the catarrhal irritation of the parts, etc., are employed.

In this connection it may be proper to allude to the practice of using bougies in the Eustachian tube, which has latterly been somewhat revived, especially on the European continent. If I could find a reasonable degree of evidence that the practice of using bougies aided in opening a tube which was insufficiently pervious, and at the same time did no harm by the traumatism thus inflicted, I might become a convert to its use. It seems to me impossible, from what experience I have had, that a bougie can be passed into the Eustachian tube, however gentle the manipulation, without inflicting an amount of violence exceeding, in the harm done, any possible good to be obtained by its introduction.

The frequency of the inflations is a very important matter. I do not often give my patients a Politzer bag for self-inflation, neither do I encourage the practice of holding the nose and pressing the air into the middle ear. I believe that an inflation should not be repeated until the augmented hearing consequent on the first inflation has become lowered. Too frequent inflation stretches the membrane, congests the tympanum, and may inflict dangerous traumatism to the middle-ear mechanism, such as stretching, or even rupturing, the ossicular ligaments, dragging the stirrup from its window, compressing the labyrinth water through pressure on the round window, etc.

So sensitive are some patients with catarrh of the Eustachian tubes that any considerable fatigue is likely to aggravate the catarrhal condition. Following this state of lowered vital energy, it, in the same connection, is often observed that such patients are much worse where the supply of nourishing food is diminished or a period of faulty digestion and assimilation supervenes. The depressing influences of cold, with insufficient clothing, acts in a similar manner, whether an active catarrhal aggravation results or not.

The influence of climate on the Eustachian tube is perhaps, in some instances, more potent than any medical or surgical treatment whatever. I am convinced by some observations that many cases of tubal catarrh, which underwent such repeated relapses as to occasion a gradual but sure progress toward profound deafness, have been completely arrested by removal to a more congenial climate. More than this, after a few years the hearing has been actually improved in some instances.

In conclusion, it may be proper to observe that the outlook in treating affections of the Eustachian tube in the somewhat unfavorable climate of this country is not as cheering as could be desired. It only remains for us to make the best of the situation, and where much cannot be accomplished be contented with less. In a general way, I have the impression that over-treatment is rather the rule, and that the opposite condition is the exception in our practice.

MEDICINE A MEAN TRADE.—The practice of medicine must be very disappointing to those who follow it chiefly for the acquisition of wealth. Whoever practises it in a commercial spirit debases the calling and degrades himself. As a French writer has truly said: "Medicine is the noblest of professions, but the meanest of trades."—*Dr. Cotting.*

MENTAL RESPONSIBILITY IN INEBRIETY.

By T. D. CROTHERS, M.D.,

HARTFORD, CONN.

THE following case outlines some facts I wish to make prominent:

John Smith, a neurotic, with an insane and hysteric ancestry, became an inebriate from hardship and exposure in the army. He drank periodically, and while drinking was either stupid and dull or very irritable and quarrelsome.

Usually he kept at work most of the time as a carriage-maker, and acted sanely on all matters pertaining to his business. The afternoons and evenings were spent in bar-rooms, drinking and talking politics. This drink period lasted from four to ten days, ending with melancholy and great prostration, from which he gradually recovered. Then a free interval of five or six months elapsed, during which he would sign the pledge, live temperately, and act in the most exemplary manner. He was in this interval a kind-hearted, generous man, rarely angry, but forgiving, and of good judgment.

When the drink paroxysm came on he was irritable and sullen. In one of these drink paroxysms he quarrelled, and threatened to kill a farmer, a near neighbor. When sober he seemed to have forgotten this anger, and was cordial and friendly to the farmer.

A year after this first altercation, while in a drink paroxysm, he borrowed a gun and shot this farmer without a word, returning the gun to the owner, and seemingly not intoxicated. He then went to an hotel and remained drinking as usual until arrested. He acknowledged the crime, saying he had "fixed him," meaning, killed the farmer, and during the ten days following in jail was stupid, indifferent, and finally very nervous. He seemed to have realized his crime at this time, and suffered from great exhaustion and insomnia. Two months later he seemed to have passed into an apathetic state, was indifferent and silent, and talked but little of himself and the crime. The quarrel with the farmer was on politics, and attracted no attention. The threats of violence seemed only the ravings of a drunken man.

On the trial, several medical men testified that the prisoner was fully sane at that time, and also at the time of the murder. That he seemed conscious of his acts and talked rationally; also, that the history of drinking did not point to insanity, or indicate that he was unconscious of the crime.

The medical men for the defence affirmed that the man was of unsound mind, that this was sustained by the facts of heredity; his drink paroxysm, the crime, its motiveless character; his changed and insane conduct during this period. They also swore that the present appearance of sanity was no reliable evidence of his consciousness or knowledge of the crime at the time, and that he was insane when the crime was committed, and without knowledge or control of his acts.

The judge charged: "That inebriety was voluntary, and always entered upon with more or less consciousness of the danger and possibility of doing wrong, hence could not be used as an excuse.

"That unless the evidence of insanity was beyond question the jury should not consider it. The fact of drinking, and the commission of crime at this period, should be regarded rather as an aggravation than as an excuse; hence, the responsibility of the prisoner would be increased if the facts alleged were true."

On this the prisoner was found guilty and hanged.

The question to us, as scientific men, is not whether this conclusion was correct legally, or in accord with the highest teachings of human justice, but was this verdict of sanity and full consciousness of his acts and their consequences true? Was this conclusion sustained by all the facts of the prisoner's life and the history of the crime?

This case is not unusual, nor different, except in minor particulars, from many others which occur in every section of the country. Persons who are not criminals in any way, but are inebriates, under the influence of or while drinking spirits, commit crime against both person and property, without malice, motive, or premeditation, and the question before the courts is, Was the man of sound mind and responsible?

Both experts and non-experts attempt to answer this inquiry by comparing the history of the prisoner and crime with that of the most pronounced types of insanity. The absence of prominent delusions, hallucinations, and deliriums, or marked mental feebleness, are regarded as evidence of soundness and responsibility. Here the physician often allows himself to be influenced by the legal rulings and definitions of insanity, inebriety, and responsibility, and unconsciously studies the facts of the history with the view of making them correspond with such rulings.

Insanity and mental disease which are without the prominent symptoms laid down in text-books are not recognized. Concealed, incipient, partial, or complex brain-diseases are regarded as not affecting responsibility for acts or conduct unless they are manifested by some well-known symptoms.

The physician has rarely an opportunity to study the case thoroughly; a few interviews in the jail gives very uncertain evidence of the mental condition of the prisoner at the time the crime was committed. The study of the previous history of the prisoner, and of his condition of life and living, requires time, and patient gathering and sifting of facts. This is absolutely essential to understand how far the brain was capable of realizing or controlling its acts.

On the witness-stand the expert is called to give definitions and lay down lines of health and disease, which unconsciously destroy the value of both his conclusions and the scientific facts of the case. As a result, these obscure border-land cases of inebriate criminals are unknown and misjudged.

Both experts and non-experts divide in their opinions of the mental soundness of these cases; the facts are not all studied; the mediæval theories of vice and wilful wickedness continue prominent, and the victims are punished by death and imprisonment. Thus, the object of the law is defeated, and the cause of justice becomes grave injustice. It is apparent that the same great wrongs are inflicted on the inebriate that marked the treatment of insanity two centuries ago.

My object is to point out some of the general principles and landmarks which should guide the physician in his study of these cases. I repeat that the teachings of the law and public theories concerning these cases are not to be considered.

The object of the physician's inquiry is to determine the mental health of the prisoner at the time the crime was committed, and to ascertain whether he could realize the nature and consequences of his acts, and had the power of self-control.

Beginning with the fact that the prisoner was an inebriate, and that the crime was committed while he was using spirits, the first study should be into the form of inebriety from which the prisoner suffered.

If a *periodical inebriate*, the character of the drink paroxysm and its duration, and the free interval, should be studied, to show how far the brain was dominated by morbid impulses.

If the drink craze was sudden, impetuous, and overwhelming, at its onset, associated with delirium and often delusions, it is called dipsomania, a distinct form of insanity and irresponsibility. The victim is controlled by a maniacal impulse, and is without clear conception or control of his acts. He has a form of epilepsy and circular insanity that cannot be mistaken.

If the periodicity is not marked by pronounced mania, its exact return at certain stated intervals is evidence of neurosis and central nerve-disease, which grows with each repetition, destroying consciousness and power of control at the time. Crime, or any act committed during those periodical attacks, cannot be the result of conscious reasoning or realization of the character or results of the act.

If the act was done in the paroxysmal stage of periodical inebriety or dipsomania, there is strong probability of insanity and irresponsibility.

The second inquiry should be of the crime, and the circumstances associated with it.

If the evidence shows that the prisoner was using spirits at or before the time the crime was committed, and also indicates no motive or reason for the act, which may be committed in a strange, unusual way, or in an exact, methodical manner, this sustains the probability of mental unsoundness. The favoring or retarding influences of the surroundings, and circumstances of the act; the reason and non-reason apparent during the commission, after or before the act, all throw light on the state of the mind at the time.

Under this head will come the complex influences of occupation, nutrition, mental and physical exhaustion, associated with the use of spirits or dependent on it.

The third general study should be of the origin of inebriety.

Here physical injuries, such as blows on the head, sunstrokes, or profound exhaustive diseases; or physical injuries which came from brain-injury, nerve shock or strain, and like causes, should be studied; also nutrient, muscular, sexual, and emotional disorders, from which inebriety is often originated or largely intensified. Where many of these causes are more or less distinct, the brain-failure and impairment can be readily traced.

Not infrequently in these cases the inebriety is merely a symptom of the brain-degeneration; the brain integrity and capacity to reason and act normally are permanently broken up. Sane conduct and thoughts in such persons are always automatic and along lines of accustomed thought and act. When they go beyond this, mental aberration and defects are apparent. Such persons have little or no control over their acts or reason, unless under the most favorable circumstances and conditions. Along this line the insanity of the prisoner can often be conclusively demonstrated.

The fourth line of study should consider the influences of heredity.

A drinking and insane ancestry points to a direct entailment of mental degeneration and feebleness, and always a more or less unstable organism, unable to bear the strains and drains of life. A consumptive, epileptic, hysteric, or odd, peculiar parentage is always followed by defective children. Inebriety and many complex neuroses date back to this cause. Defects of reason and control are transmitted as positively as external forms and peculiarities.

Where the parental degeneration dates further back, it may be less prominent, but it is always a factor. An heredity associated with inebriety from neurotic ancestors gives strong indications of insanity and irresponsibility.

If the facts in evidence on these four points of inquiry sustain one another, the conclusion of insanity is inevitable.

If the inebriety was periodical, or had the form of dipsomania; if the crime was unusual in circumstances, surroundings, and without apparent motive; if there was a history of traumatism or exhausting disease of severe injury; and if to this was added an heredity direct or indirect, the chain of evidence pointing to insanity and irresponsibility is more or less complete; if the evidence on any one or more of these points is wanting, as, for instance, on heredity or traumatism, the irresponsibility of the victim may still be found. These are only outlines of the ranges of facts which must be ascertained in the question of responsibility.

Exhaustive studies of these cases will often indicate the changed character, habits, temper, emotions, and reason that have been noticed by only intimate friends, not only when the subject was under the influence of spirits, but when free from them. These are some of the factors from which to determine the mental capacity of the prisoner.

The medical examiner should always remember that the use of alcohol, continuously or at intervals, produces changes of brain-circulation, vaso-motor paralysis, congestion of the brain-centres, disturbances of nutrition, and many other changes. Also, that the use of alcohol in moderation or excess impairs both brain and nerve function, and imperils the integrity and capacity of the brain.

The use of spirits is often a symptom of brain-disease, as well as an exciting cause, and the character of injury produced from the use of alcohol in any way cannot be clearly determined.

From this basis of facts the following general conclusions may be stated:

1. The knowledge of right and wrong is no evidence of the mental health of the prisoner; his ability or inability to control or restrain himself are the real tests of responsibility. In determining this, the question of morbid impulses, of the craving for spirits, and of the control or domination of the passions over the reason must be studied.

2. The toxic use of alcohol brings on a degree of brain-paralysis, with delusions and hallucinations, all of which may be concealed, except from a careful study.

3. The absence of all prominent symptoms of insanity in an inebriate is no proof that he is sane; the appearance of sanity and of the power of control of his acts is often only the twilight of a mental condition that is gone.

4. The fact of using spirits persistently, and to excess, so prominent in all these cases, indicates a form of mania; also, loss of self-control, and incapacity to realize the nature and character of his acts.

5. In all these cases there is a physical element, in which local paralysis, or perversions of brain-centres, may exist. Trance and hypnotic states, the direct or indirect result of alcoholic ethers, may make the victim fully unconscious and irresponsible.

6. Nothing but an exhaustive study of all the facts in the history of these cases will reveal the actual condition and measure of responsibility. Anything less than this will fail, and result in great wrong and injustice.

The charge of Judge Edmonds, cited by Dr. Mann,[1] gives a correct view of the general principles which apply in these cases.

"To be a criminal, a man must have memory and intelligence to know that the act he is about to commit is wrong, and that he will be subject to punishment, also reason and will to enable him to compare and choose between the right and the wrong.

"If he has not intelligence and capacity to have a criminal intent and purpose; if his moral and intellectual powers are so deficient that he has not will, conscience, or controlling power; or if from violence of mental disease his intellectual power is for a time obliterated, he should not be held as responsible or punished for his acts."

I conclude this outline-study with a general summary, which may be said to represent the latest facts and conclusions on this point.

1. In all cases of inebriate criminals there is mental defect, and incapacity either to reason sanely or to control their acts. An inebriate who does criminal acts cannot be of sound mind. A criminal who is an inebriate is not sane. No inebriate is fully sane, and no criminal can be of sound mind long.

2. The question for the medical witness is, How far

---

[1] See Journal of Inebriety, July, 1884.

was the prisoner conscious of the nature of his acts? and How far did he have control over his acts in a certain crime?

3. John Smith has committed a crime while under the influence of alcohol, and the law inquires into his mental condition at the time of the crime. His impaired mental health and responsibility is beyond doubt.

Is it possible from a study of the facts in the history of the prisoner to determine the ranges of responsibility and accountability? Can we go into this penumbra region of sanity and insanity, and follow vice up to the dead lines of disease, and show where human justice should punish, and where it should forgive, as irresponsible?

4. The medical man approaches this problem from the scientific side, seeking the facts beyond all moral or legal theories of brain-action. There should be no hesitation in stating what appears to be the truth, no matter how far it is beyond the popular intelligence of the present.

5. If the facts in the history of the prisoner point to a degree of unconsciousness of the nature and character of his acts, and the inability to control such acts, the insanity of the prisoner should be assumed as a fact far more likely to be true than the opposite. The limits of scientific study will not sustain any efforts to draw boundary lines where health and disease join.

6. When the fact of the inebriety of the prisoner is established, his sanity in a given case must be proven and sustained beyond all question or possible doubt. All the circumstances and conditions of the crime and life of the prisoner must bring evidence to prove this fact.

The general fact of inebriety reverses the natural order; his insanity must be assumed, and his sanity proven.

7. Finally, in all these cases, the medical witness is called to determine the physiological, pathological, and psychological facts and their meaning. The applications of these facts are for the law, court, and jury.

The medical expert of to-day must go beyond the theories of yesterday, or the facts on which yesterday's views were based. A newer, larger field opens up to-day, and the facts are more numerous, and indicate a clearer, wider view to-morrow.

Death from Fright.—Instances in which persons have been known to die as a result of some fright are not very uncommon, but in most cases it is really heart disease to which the death is rightly attributable, the fright acting merely as an exciting cause by throwing a little extra burden upon this already overtaxed organ. A few cases of death from pure fright have, indeed, been reported by Manson, Cazenave, and others, but well-authenticated instances of the occurrence are rare enough to possess considerable interest. The following case is reported by Dr. Annibale Montalti, in *Lo Sperimentale*, No. 10, 1887: A lady accompanied her husband one day to their estate in the country, and was present when he got into an altercation with one of his tenants. The dispute ran high, and the men were just on the point of coming to blows, when the lady exclaimed, "I am dying," and fainted. She was carried to a bed, and soon died, in despite of the efforts of a physician, who had been summoned. The only lesion found at the autopsy was a very slight aortic insufficiency, a few drops filtering through when the aorta was filled with water. There were also slight atheromatous changes in the aorta and on the aortic valves, but none of the lesions was of sufficient importance to have weakened the heart to any appreciable extent. This case may, therefore, be added to the few already reported of death occasioned by pure fright without any other sufficient cause being discoverable.

Progress of Medical Science.

Rupture of the Rectum from a Fall.—The following case is reported by Mr. Thompson, of the Manchester Royal Infirmary (*The Lancet*, December 3, 1887): C——, aged eighteen, was admitted on May 20, 1887. He stated that he had fallen about four feet, in a sitting posture, on to the end of the upright shaft of a smith's hammer, which he described as having entered his seat for a considerable but unknown distance, and requiring some amount of force in its removal, which was accomplished by a fellow-workman. He had very little pain at the time of the accident, and walked about a mile to the infirmary without much trouble. On examination only some slight bruising was found around the anus, with a little blood-stained mucus. Per rectum nothing was detected. The abdominal walls were quite flaccid. Examination caused no pain. He complained, however, of a slight, continuous, aching pain just above the pubes Soon after admission he passed both urine and fæces, the former normal, the latter soft and streaked with blood. Some hours later he passed another motion, with a considerable quantity of clotted blood; the suprapubic pain also became more intense, but the abdominal walls still remained flaccid. The face was very pale, the pulse rather weak, and the extremities cold; but the patient appeared to be in good spirits, answered questions readily, and did not feel unwell. He remained in this condition until midnight, when the abdominal pain became more severe. Symptoms of collapse gradually came on, and he died at 8 A.M. At the necropsy, on the same morning, the peritoneum was everywhere found intensely injected, and in parts presented a thin layer of lymph. There was a marked laceration in the recto-vesical pouch, a little to the right of the middle line, which led into a triangular opening in the wall of the rectum, about three inches from the anus; this aperture was triangular, its base measuring one inch and a half, its sides an inch each. At the brim of the pelvis, on the right side, was a laceration of the peritoneum covering the psoas, with bruising of the subjacent muscle. The mesenteric glands were enlarged and inflamed. The abdominal cavity contained a small quantity of hard fæces; there was also found a piece of cloth corduroy, two inches long and one inch and a half in breadth, corresponding in texture to the patient's trousers and to an aperture in their seat.

The Salicyl Compounds in Rheumatism.—In a paper on the treatment of acute rheumatism by salicylic acid and allied drugs, Dr. Alfred H. Carter, of Birmingham, discusses, among other points, the circumstances under which these remedies are alleged to fail. Probably the most common source of failure consists in a faulty mode of administration. Either the drug is not given in sufficiently large doses or not at sufficiently short intervals. For a young adult, in a case of average severity, the doses should not be less than twenty grains, nor should the intervals between them exceed three hours. In cases of unusual severity the dose should be repeated every two hours. Of course it is not necessary to maintain this high dosage. As soon as the symptoms begin to yield, the quantity should be gradually diminished. Failure in other cases may be explained by the fact that inflammatory changes have been set up in the joint, which are too severe and deep-seated to subside immediately on the removal of the primary irritation. The salicylates remove the latter, but have no direct influence over the inflammatory changes in the joint. The salicyl compounds always answer best in the early stages of the disease, before the joint mischief has had time to make any headway. Again, if the drug be suspended during the early days of the fever, relapse is practically certain; later on, relapse is less likely to occur, until at last, when the metabolic disorder which constitutes the essence of the rheumatic process has naturally subsided, relapses do not occur at all. It is necessary to continue the use of the drug, in reduced doses, for at least three weeks from the date of onset; and even then, on the slightest return of symptoms, to recommence its administration and to continue it at least for another week or ten days. In this light, so far from the occurrence of relapses depreciating the practical value of the drug, they show up the specificity and certainty of its operation, within its own limits of activity, in a most striking manner. With reference to heart-complications, Dr. Carter believes that they occupy exactly the same secondary relation to the chemical changes in the blood as does the joint-affection. Consequently, in the same manner as the joint-inflammation can be prevented by early and vigorous salicyl treatment, cardiac inflammation may be prevented. He has never seen cardiac complications occur after the first twenty-four hours of salicyl treatment in a case which was known to be uncomplicated at the outset, and in which it was clear, from the rapid diminution of the joint-pains and fever, that the patient was properly under the influence of the drug. When such complications occur during the first days of treatment, it is probable that the inflammation had already begun when the patient first came under observation; and, as with the joint-inflammation, the salicylates have no direct influence of any kind on the inflammatory mischief *per se*.—*The Practitioner*.

Medical Missionaries.—In very many of the missions for the spread of evangelical Christianity among heathen nations the physician is regarded as almost as essential as the clergyman, and it is through the good results of the former's ministrations that the latter is enabled to gain a hearing. This is an eminently practical way of reaching the heathen, and to it is doubtless due the greater part of whatever success these missions have had. There ought to be little difficulty in securing medical missionaries enough to supply the demand. There is little attraction, for a young graduate without means or unusual abilities, in the prospect of a long struggle after a practice sufficient to support him in even comparative comfort in civilized countries. But the thought of a journey to distant lands, plenty of congenial work to do, and a support from the start, is pleasing to many even who may be but little influenced by the religious aspect of their calling. And when to this is added the powerful attraction of religious work to a truly pious mind, the impulse to offer one's self for the mission is wellnigh irresistible. But it is well to look at the dark side of such a life before entering upon it, for after the work is once begun it cannot be laid down lightly and without good cause. A medical missionary should, above all, be a thoroughly educated physician, not merely a graduate who has passed a creditable examination and has attended a few clinics. He should be one who has studied disease practically as a hospital interne, and who is competent to treat any affection of any organ—the eye, the throat, and the ear, as well as the heart, the lungs, or the stomach. He should, of course, be thoroughly in sympathy with the religious work of the mission, for he is to be a missionary as well as a physician; indeed, the primary reason of his going is to pave the way for the conversion of the people among whom he is to live. Finally, he should be not only healthy, but of robust physique and iron constitution. He is going to a new climate, and one that is often most trying, if not deadly, to people from temperate regions, and he will be, by reason of his work, more exposed than any others of his companions to the dangers of this climate. Then, again, the medical missionary is sometimes exposed to considerable personal danger at the hands of ungrateful patients, or of the ungrateful friends of patients. The heathen are no better than other people. When a case goes wrong they abuse the physician just as roundly as good Christians do, and their abuse is apt to be even more active and to express itself by the attempt to inflict bodily injury rather than damage to reputation and good name. Medical missionaries in China and elsewhere have been forced to flee for their lives to escape the fury of an angry mob of the friends of some patient who had unfortunately died after an operation. We have no desire to discourage young men or women from embracing the calling of a medical missionary, but it is better to put the facts plainly before them while they are still here, than it is for them to learn them after they have journeyed thousands of miles and have found themselves in a position from which they cannot honorably retire. The medical missionary societies do all they can to put the matter in a proper light before their candidates, but it is hard to restrain enthusiasts, who believe that they have a vocation, from embracing it, in despite of any and all obstacles which may be thrown in their way.

An Unreliable Sign of Death.—Among the signs of death which have usually been considered the most certain is that of the explosive air-bleb. If the flame of a candle be brought close to the finger of a dead person the skin will be observed to become dry, and air will collect beneath it, raising it up in a blister, which will finally break with a slight noise. In a living person, under the same irritation, there will usually be formed a bleb containing serum. This has been supposed to indicate certainly that the person was dead, but a case reported by Dr. Martel, in the *Revue Internationale des Sciences Médicales*, No. 9, 1887, goes to show that the sign is not an infallible one. A woman attempted suicide by inhaling charcoal fumes, but was discovered before life was extinct. In the efforts at resuscitation cupping was employed, and the skin was accidentally burned. It was noticed that the blister resulting contained air instead of serum, and on approaching the flame of the candle to the finger an air-bleb was formed and broke with a slight explosion. The woman, though insensible, was breathing regularly, and the heart was acting well. The signs of death resemble those of pregnancy in their uncertainty, and in doubtful cases of either condition no single symptom can safely be relied upon, but a conclusion must be reached by a careful weighing of all the indications present.

Recurrent Attacks of Scarlet Fever.—Authentic cases are on record in which scarlet fever has attacked the same person twice or even three times. Yet such recurrences are rare; and Dr. Willan, quoted by Aitken, asserts that among two thousand cases of scarlet fever he had never seen a second attack. On the other hand, the sore throat which so often accompanies a scarlet fever epidemic seems often to attack even those who have had the disease. Some physicians, like the late Dr. George B. Wood, can never attend scarlet fever patients without suffering from a slight angina. It has been thought that perhaps the scarlatinous virus may appear in a modified form many times, and Dr. Frank, a German physician of many years' experience, suggests (*Allgemeine Med. Central-Zeitung*, 1887, No. 100) that mild forms of diphtheria are illustrations of this idea. He has been impressed with the belief, also, that an attack of scarlet fever gives a certain degree of immunity against diphtheria, this latter disease appearing in a milder form in those who have suffered from the exanthematous fever. In illustration of the view that the virus of scarlet fever may attack a person a number of times, he cites the case of a boy of thirteen who, between the years 1880 and 1887, had four different attacks of typical scarlet fever, the later attacks being, on the whole, milder than the first. It has been claimed for some infectious diseases that persons who do not secure immunity by one attack never secure it, and are liable to the disease an almost indefinite number of times. The subject of recurrence of scarlet fever is an important one, and doubtless our readers can contribute to it from their experience.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY

WM. WOOD & Co., Nos. 56 and 58 Lafayette Place.

New York, February 18, 1888.

THE NERVOUS ORIGIN OF RHEUMATOID ARTHRITIS.

PROBABLY the bulk of the profession has accepted the opinion of Charcot regarding the nervous origin of those arthropathies which are now commonly included under the designation of "Charcot's disease." But concerning the etiology of rheumatoid arthritis, or, as many prefer to call it, arthritis deformans, there is a much wider divergence of professional opinion. The subject was recently brought before the Royal Medical and Chirurgical Society, by Dr. A. E. Garrod. This gentleman based his views on the study of five hundred cases of arthritis deformans. Arguments were put forward by Garrod in support of the following propositions (*The British Medical Journal*):

1. The causes of rheumatoid arthritis were such as might be expected to act upon the central nervous system. 2. The distribution of the lesions was such as would be likely to result from nervous lesions. 3. The distribution of the lesions was similar to that of certain arthropathies of spinal origin.

The influence of heredity was then discussed. In 216 cases out of 500 there was a family history of joint-disease, sometimes of more than one variety. There was a history of gout in 86, of probable gout in 10, of rheumatism in 64, and other conditions, which might be classed together as probably rheumatoid arthritis, in 84. These figures could only approximate to accuracy, as they were based upon information given by the patients.

The influence of uterine causes was then taken up, and it was shown that when the female cases were arranged according to the age of the patients when the disease commenced, there was a steady increase in numbers up to the period of the menopause, and a steady decrease after that period. Of the 500 patients 411 were women, and only 89 men. The influence of anxiety and care, mental shock, injuries, damp, cold, and previous rheumatic attacks was discussed, and each of these was shown to have a share in the causation of the disease. Stress was laid upon the extreme symmetry of the joint-lesions in rheumatoid arthritis. There was a tendency for the joint-lesions to advance up the limbs from the periphery toward the trunk. This order of invasion was by no means constant, but in particular instances it was well marked. In the localized form of the disease it was of course absent. The knees ranked only second to the hands in liability to rheumatoid arthritis. Garrod also pointed out that there was a close resemblance between the distribution of the joint-lesions in rheumatoid arthritis and in the recorded cases of arthritis following spinal concussion, whereas in more local spinal injuries one or more large joints were usually affected, as in tabes dorsalis. The associated nervous phenomena, such as muscular wasting, increase of tendon-reflexes, etc., were regarded as secondary to the joint-lesions, and as therefore lending no efficient support to the theory of the nervous origin of rheumatoid arthritis.

In the discussion which followed the reading of this interesting communication, Sir Dyce Duckworth agreed with Garrod in believing that rheumatoid arthritis was of nervous origin. He added, which is no doubt quite true, that the minute anatomy of the nerves about the joints was still very imperfectly known in this disease. Trophic changes might easily occur, however, without palpable nerve-lesions.

Dr. Buzzard, on the other hand, found some difficulty in convincing himself of the nervous origin of rheumatoid arthritis. He had said eight years ago that probably there was some part of the medulla presiding over the nutrition of the skeleton. And some acute medullary affection he still considered the cause explaining the acute sweating of rheumatism, its hyperpyrexia, and cardiac disease. The evidence of nervous origin of rheumatoid arthritis was, at any rate, very much less decisive than in Charcot's joint-disease. Its symmetry made it probable, but there was not the concomitant trophic disturbance of a nerve-disease.

From all of this we may conclude that, while the mode of origin of rheumatoid arthritis is still rather obscure, the time is past when it can be ascribed to that convenient *fons et origo mali*, "a cold." Doubtless dampness, cold, and similar influences are not wholly without their effect. But there are other factors, more directly acting upon the nerve-centres, that we cannot afford to overlook.

CARCINOMA AND SYPHILIS.

IN a communication in *The Lancet*, on the subject of the contagiousness of cancer, noticed recently in these columns, Mr. Clement Lucas referred to syphilis as being often contributory to an outbreak of carcinoma. Others have expressed the same opinion as to the existence of a causal relation between the two affections, but have not brought forward any very satisfactory evidence in support of their views.

In a paper read before the Texas Medical Association, in 1884, Dr. Edmund Goldmann, now of San José, Cal., took the opposite ground, that there exists an antagonism between syphilis and carcinoma, so that the former disease, instead of predisposing to cancer, is rather preservative against its ravages. The writer stated that Dr. Scheuthauer, formerly Rokitansky's assistant in Vienna, had told him that in several thousand autopsies which he had made personally, he had never seen the lesions of carcinoma and syphilis in the same body. This statement had made a strong impression on him, and during a professional life of five years in Mexico, where he had had an opportunity to study a large number of cases of syphilis, he had been on the lookout to discover an instance of the coexistence of these two affections, but had yet to see it.

The following are Dr. Goldmann's conclusions in the paper above mentioned: "I may condense the result of my experience in stating that I have never met the two affections in the same person, and, according to my view, the one excludes the other. While carcinoma holds for a long time the position of a parasite or a foreign body growing within the human body, syphilis is, from its beginning, an infection, like that of glanders, with which it was confounded by the physicians during the siege of Naples. The two diseases, therefore, have nothing in common with each other." Syphilis, he adds, is extremely common among the men in Mexico, while cancer is rare.

ŒDEMA OF THE NEW-BORN.

In a communication presented to the Academy of Medicine of Paris, on November 8th, Dr. L. Dumas called attention to the striking analogy between œdema neonatorum and phlegmasia alba dolens. These two affections resemble each other, he said, not only in their symptoms, but also in their etiology and pathological anatomy. But it had not hitherto been shown, though suspected by some writers, that there is a thrombosis existing as the cause of the œdema in the new-born. The writer had, however, found thrombosis of both femoral veins in a case of this affection recently examined post-mortem by him.

Although not presuming to assert dogmatically, after a single examination, that this is the sole lesion of the affection, the author offers the following theory of the nature of the disease: The œdema, which has been shown by Parrot to be entirely distinct from sclerema, with which it was formerly confounded, affects chiefly weak and sickly infants, the type of which is the prematurely born, which may be compared to cachectic organisms, in whom, as is well known, there is a predisposition to spontaneous thrombosis. The incomplete respiration, a consequence of the general weakness, induces a retardation of the venous circulation, which favors a coagulation of the blood, especially in the incompletely emptied umbilical vein. Phlebitis of the umbilical vein may also be a direct cause of thrombosis.

The two practical conclusions which the author draws from his study of this affection are the following:

1. The treatment of œdema neonatorum should be the same as that of phlegmasia alba dolens. Especial care should be taken to provide a sufficient amount of heat, for which purpose Tarnier's *couveuse* is especially useful. Every means should be used, also, to increase the functional activity of the lungs.

2. It is necessary to abstain absolutely from the practice of massage, which is recommended by many authorities, since it exposes to the danger of breaking up the thrombus and thus giving rise to embolism. Possibly the pulmonary troubles so often met with in this disease may be excited, in some cases at least, by fragments detached from the thrombus and lodging as emboli in some portion of the lungs.

Whether the author is right in his assumption, that œdema of the newly born is essentially the same disease as milk-leg in the parturient woman, can only be determined from the results of numerous autopsies of infants dying with this affection. Thrombosis certainly offers a reasonable explanation of cases of localized œdema, but it would hardly appear to account satisfactorily for those cases in which the œdema is very extensive, involving the upper extremities, trunk, and at times even the face. Nevertheless, the conclusions of Dr. Dumas regarding the treatment are sound, and may safely be followed, whether his views as to the pathology of the disease are accepted or not.

THE CURE OF DEAF-MUTISM.

Whatever may be the disadvantages and dangers of specialism in medicine, no one can dispute that the general sum of knowledge has been vastly increased by the labors of special workers in different departments Many affections, the nature of which was unknown or misunderstood, have been set forth in their true light, and, being better understood, have come to be more rationally and successfully treated. Deaf-mutism, for example, was formerly regarded as a congenital affliction, and one for which there was no remedy. The labors of otologists have shown, however, that it is frequently due to loss of hearing—the result of ear disease in infancy—and that the deafness so caused is often amenable to cure, or at least improvement, by proper treatment.

In the *Revista de Ciencias Médicas* for December 10, 1887, Dr. D. P. Verdós reports two cases which well illustrate this point. The first case was that of a boy, five years of age, who was a mute. The parents noticed that the child did not begin to talk at the usual age, and after waiting a while in the hope that he might commence to lisp a few words, they consulted their physician. The only explanation that he could offer was, that there was probably some trouble with the hearing, which might eventually disappear. After waiting a few years more, and hearing no articulate sound from the boy's lips, they took him to Dr. Verdós' clinic. Examination at this time showed an apparently total loss of hearing. The only hope lay in the fact that the child gave evidence of a slight perception of the sound of the tuning-fork applied to the walls of the cranium. Further examination showed that the loss of hearing was due to a catarrh of the Eustachian tube, occurring in infancy, which had caused a closure of its lumen, the rarefaction of the air in the tympanum being evidenced by the enormous retraction of the drum-membrane. Treatment was now commenced by catheterization of the Eustachian tube and forcible inflation by air douches, assisted by rarefaction of the air in the external auditory canal. By these measures the drum-membrane was restored to its normal position, and within the space of two months the boy was able to hear sounds of all kinds, including the ticking of a watch held at some distance from the ear. He soon began to utter a few monosyllables, and rapidly learned to talk with as much ease as any child of his age.

The history of the second case, that of a child four years of age, was similar to the first, though his acquisition of speech was not as rapid nor as perfect, owing, evidently, to mental defect.

These cases are instructive, showing, as they do, that deaf-mutism is not always an irremediable condition, but that, in certain cases at least, proper treatment will save the child from this affliction. They prove, also, that it is not too late to make the attempt to restore the hearing, even after the lapse of several years; and if a child five years old can be saved from this fate, it is not too much to hope that one even older might acquire hearing and speech as a result of intelligent and persistent treatment.

VIRCHOW ON CANCER.

In the current issue of *Virchow's Archives* is a long article, by Professor Virchow, on the pathology and diagnosis of cancer. The article is largely historical, and gives a review of the facts regarding the pathology of cancer now generally accepted. As is well known, Virchow was the first to place the pathological anatomy of cancerous growths upon a sound basis. His share, as he justly claims, in this work consisted in demonstrating the alveolar type as common to all carcinomas, and not merely to the simple and gelatinous forms (which latter had alone been termed "alveolar" by Otto); and then to prove that the cancer-cells were of the type of epithelial or epidermal cells, especially those of so-called transitional epithelium. He adds that Alibert is incorrect in saying in his recent work that Johannes Müller was the first to discover the epithelial character of cells in a case of cancer of the cheek. Müller's statement is: "I once saw epithelioid, flat, squamous-looking cells, with nuclei forming a thick layer on the surface of a cancer of the cheek—obviously an epidermal layer."

There is, then, a twofold test of carcinoma, the closed alveoli and the epithelioid cells they contain. It is plain that this structure can only be found in the depth of the tissues, and not on the surface, although in its growth it may come to project beyond the surface. The diagnosis therefore turns upon the point whether the growth is actually seated below the surface; whether it is, in fact, heterologous in the sense in which Virchow uses that term. Cancer begins with the development of epithelium in abnormal situations, and the proof of such abnormality (heterotopia) is the first step in diagnosis; but it does not end there, for other tumors—as pearl tumors and dermoids—produce heterologous epidermal structures, and are certainly not cancers. The growth must have the appearance of a gland, but with closed outlet.

With regard to the bacillus, Virchow says: "It is possible such may exist; indeed, such a discovery would constitute an important advance . . . which might explain much that is still obscure as to the metastatic processes which occur in cancer." But gland-cells have been shown to produce various tissue-products, and cancer-cells alone amply suffice to explain the constitutional effects of cancer. That cancer is always primarily local in character, and that its dyscrasia was always secondary, was contended for in the "Handbook of Special Pathology" as early as 1854, a time when the "cancerous constitution" was still firmly believed in.

On the question of the cure of cancer it says: "Dittrich showed that cases of supposed retrogression of cancer of the liver were really due to gummata; but Virchow has observed a cicatricial process in hepatic cancer caused by fatty metamorphosis of the cells in the centre of the tumor. 'The formation of accessory foci is what forms the obstacle to a real healing. Cancer itself is no permanent tumor.' Indeed, its cells have a very restricted vitality. Regarding medicines, Clay's treatment with Chian turpentine is mentioned, and the author is of opinion that though as yet no satisfactory proofs of cure are afforded, the profession is generally too sceptical on this subject. Von Nussbaum attempts to set up fatty degeneration in a tumor by thrusting the thermo-cautery in different directions beneath it, and thus depriving the periphery of its vascular supply. All such attempts are commended. 'If cancer is at first, and often for very long, a local disease, it must be possible at this stage to cure it locally.'"

News of the Week.

Care of the New York Insane.—A strong effort is being made by the State Charities Aid Association to secure a law providing that the insane in all the sixty counties of this State, except New York, Kings, and Munroe, shall be taken care of in State institutions. There are now, exclusive of the three counties mentioned, about two thousand insane in county institutions, scattered in the various poor-houses and almshouses of the State. To erect the buildings required for their accommodation on State asylum grounds, an appropriation of about $500,000 would be necessary. The State has already appropriated over $6,000,000 for the better care of its pauper insane. The prominent features of the law are the following: 1. The districting of the State into as many asylum districts as there are State hospitals or asylums for the insane. 2. The reception by the State hospitals of all the pauper insane, both acute and chronic cases, from all the poor-houses and almshouses of the district to which the State hospital belongs, at a uniform weekly rate per capita, charged to the counties for each pauper insane person so received, whether an acute or chronic case, of $1.50. This payment is to include clothing and travelling expenses. An attendant trained in the State hospital for the purpose shall be sent for and will accompany the insane person to the State hospital. 3. The erection on the grounds of the existing State hospitals of a number of inexpensive detached buildings sufficient to provide suitable accommodations for the chronic pauper insane now in the poor-houses and almshouses of the State at a cost not to exceed $250 per capita. These buildings to be erected, if possible, within one year after the appropriation is made.

The Committee of the Medical Society of the State of New York, to whom was committed that portion of the President's opening address relating to the treatment of the insane, would respectfully report:

1. That until comparatively recent times the insane were considered and treated as criminals and confined in dungeons or prisons.

2. Their subsequent retention in poor-houses was but a remnant and mitigation of the old system.

3. The treatment of the insane has improved with the progress of civilization.

4. Therefore special hospitals were supplied for them, and their welfare was intrusted to scientific and humane experts.

5. To return to anything like the old system of treating the insane in poor-houses or relegating them to the custody of county officials would be a grave mistake.

As early as 1855, at a meeting of the county superintendents of the poor, held at Utica, the following, among other resolutions, was passed:

"*Resolved*, That no insane person should be treated or in any way taken care of in any county poor- or almshouse or other receptacle provided for, and in which paupers are maintained and supported."—"Fifty-fifth Annual Report, State Asylum at Utica."

6. For the proper classification and treatment of the insane more means are required than for the patients of general or even other special hospitals. Institutions for the insane therefore demand medical experts as superintendents, nurses trained in the general care of the sick and then in the special care of the insane, schools for the physical and intellectual training of the insane, for the practice of out-door and in-door industries, and many other appliances.

7. The Medical Society of the State of New York expresses therefore its objections to any plan or law which in any way looks to the return of the insane to the county poor-houses as being unscientific and inhumane, and expresses its conviction that those institutions, like the State Asylum, which have Boards of Managers accountable to the State government and also to the public, are best adapted for the care of the insane poor of the State.

All of which is respectfully submitted.

A. JACOBI,
C. R. AGNEW.

Adopted, February 9, 1888.

Resolved, That the above report on the treatment of the insane be sent to the Committee on Legislation of the Medical Society of the State of New York, with instructions to use it in its discretion in the Legislature and elsewhere to further the objects in view.

In the discussion which followed the following was read as illustrating the progress which is being made in the scientific nursing of the insane, a kind of progress not likely to reach the insane if shut up in poor-houses:

"Extract from letter of Dr. Joseph M. Cleveland, Medical Superintendent, Hudson River State Hospital, Poughkeepsie, N. Y., to Amasa J. Parker, Jr., President of the Board of Managers of said hospital.

"Dated February 5, 1888.

"Next month (March) we graduate four young women from our Nurses' Training School. All four before coming here had graduated from a General Hospital Training School. They will have been with us one year in March. They have been very thoroughly instructed in mental nursing by lectures, class instructions, quizzes, and clinical teaching. They are bright, intelligent, and full of ambition to become thoroughly equipped in all that pertains to a high order of nursing."

LONG ISLAND COLLEGE HOSPITAL.—The commencement exercises of this institution will be held at the Academy of Music on Friday, March 9, 1888, at 8 P.M. Rev. T. DeWitt Talmage, D.D., will deliver the address to the graduates, and the valedictory will be given by George W. White. Professor A. Jacobi will address the Association of the Alumni of this College on Monday, February 27, 1888, at 8 P.M., at the College building. The subject of his paper will be "The Heart and Blood-vessels of the Young." The Annual Dinner of the Association will occur on Thursday, March 8th, at 7 P.M., at Remsen Hall.

OFFICERS-ELECT OF THE NEW YORK COUNTY MEDICAL ASSOCIATION.—At the last meeting of this Association, held January 16th, the following were elected: *President*, J. R. Macgregor; *Vice-President*, C. S. Wood; *Recording Secretary*, Frank Grauer; *Corresponding and Statistical Secretary*, J. W. Small; *Treasurer*, C. Ellery Denison; *Member of Executive Committee*, Charles A. Leale.

THE ANNUAL DINNER OF THE ALUMNI ASSOCIATION OF BELLEVUE HOSPITAL MEDICAL COLLEGE was held at the Hotel Buckingham on Tuesday evening last, and was in every respect the most successful gathering which this organization has yet held. Among the guests were Commissioners Porter and Brennan, Rev. Dr. Armitage, Rev. Dr. Lloyd, Dr. C. R. Agnew, Dr. F. P. Foster, Dr. C. L. Dana, and Mr. William A. Purrington. The President, Dr. Webster, was in the chair, and numerous toasts were responded to by the guests. The Association has reason to congratulate itself upon its rapid growth and prosperity.

PROFESSOR W. T. COUNCILMAN, Associate in Pathology in the Johns Hopkins University, has been elected to the Chair of Anatomy in that institution. Professor Councilman is a native of Maryland, and a graduate in medicine of the University of Maryland, of the class of 1877.

THE TRUE FIELD FOR TEMPERANCE WORK is among physicians. Such is the view taken by "an excellent but mistaken clergyman," who sends a paper setting it forth to the *Journal of Inebriety*. This view he believes to be true "from the fact that a large number of physicians were intoxicated at the banquet at the International Medical Congress at Washington." The editor of the *Journal* says, however, that only one man was visibly intoxicated out of three thousand. "A half a dozen or more were exhilarated, and showed the transient excitement of wine. A dozen or more had marks of being inebriates, but seemed to be abstaining at that time. It was clearly evident that the American physician, as seen at this place, was far more temperate, as a class, than the average man in other callings of life."

THE WILLIAM F. JENKS MEMORIAL PRIZE.—The First Triennial Prize, of Two Hundred and Fifty Dollars, under the Deed of Trust of Mrs. William F. Jenks, will be awarded to the author of the best essay on "The Diagnosis and Treatment of Extra-uterine Pregnancy." The prize is open for competition to the whole world, but the essay must be the production of a single person. The essay, which must be written in the English language, or if in foreign language, accompanied by an English translation, should be sent to the College of Physicians of Philadelphia, Pennsylvania, U. S. A., addressed to Ellwood Wilson, M.D., Chairman of the William F. Jenks Prize Committee, before January 1, 1889. Each essay must be distinguished by a motto and accompanied by a sealed envelope bearing the same motto and containing the name and address of the writer.

Clinical Department.

A NEW MYDRIATIC AND NARCOTIC—ASTRAGALUS MOLLERSIMUS—THE "LOCO" PLANT.

By ISAAC OTT, M.D.,

EASTON, PA.

In a series of experiments published in the journal *New Remedies*, August, 1882, I found that astragalus mollersimus decreases the irritability of the motor nerve, and affects the sensory ganglia of the central nervous system, preventing them from receiving impressions. It also has a spinal tetanic action, killing mainly by arrest of the heart. It reduces the cardiac force and frequency, temporarily increasing arterial tension, but finally decreasing it. It has a stupefying action on the brain, increases the salivary secretion, and greatly dilates the pupil. The diminution of sensibility by this drug and its slowing action on the heart show that it would be an important medicinal agent. In my previous observations no experiments were made as to the local effect of the astragalus upon the pupil. Recently, on account of the great rage for mydriatics, I have tried it upon the eye of the rabbit. The alcoholic solution of the drug, about two fluid drachms, was allowed to evaporate in the air, and the residue was rubbed up with a drachm and dropped into the eye. In about fifteen minutes the pupil of the rabbit's eye was seen to be considerably larger, and remained so for some time. In my own eye a few drops of the above watery solution also caused dilatation of the pupil. The admixture of the vegetable tissues with the active principle of the drug prevents any extended experiments upon the pupil. It is to be hoped a chemical extraction of the active principle will soon be made. The dilatation of the pupil and the narcotic action of the drug explain the disposition of animals who have been "locoed" to mistake a rut for a larger opening in the ground, and make a great leap to avoid it.

PENETRATING WOUND OF NECK, INVOLVING THE COMMON CAROTID ARTERY AND INTERNAL JUGULAR VEIN—LIGATION—HEMIPLEGIA—RECOVERY.

By E. P. SWASEY, M.D.,

NEW BRITAIN, CONN.

Shortly after 2 P.M. of June 2, 1887, I received a telephonic summons to come to East Berlin, a small manufacturing village five miles distant, the person at the telephone stating that a man had been wounded in the neck and was bleeding badly. My reply was to apply pressure directly to the wound, and maintain it until my arrival.

Ordering a conveyance, getting necessary instruments, and calling Dr. H. C. Deane, my next-door neighbor, occupied but a few moments, and thirty-five minutes after I had received the message we had driven six miles (having gone a mile out of the way), over hilly roads, heavy from recent rains, and were at the side of the patient, whom we found lying on a bench in the corner of a lathe-room, his clothing covered with blood, in front, to his feet, the master-mechanic of the shop, a large, powerful man, calmly standing by his side, pinching the edges of the wound together, and effectually checking the flow of blood. The pulse was strong and slow. It was evident from the situation of the wound and the amount of blood already lost that we had a serious wound to deal with.

The man, aged forty, had been employed in holding what is termed a set-hammer, at a place some three hundred feet distant from the lathe-room. This set-hammer, the face of which was very ragged, and held with the outstretched hand on a level with his neck, was being struck from above by another hammer, when a chip from the face of the former was broken off and struck the patient in the neck. Grasping his neck and jumping from the flat-car on which he had been standing, he hastened toward the shop, the master-mechanic meeting him on the way and assisting him to the place where we found him. The scale of iron, which was afterward found in the wound, was about half an inch square, very thin, and with exceedingly keen edges, and must have been projected with great force.

The patient was now brought around to a good light on the table prepared for him, and we found, on examination, a transverse wound, cleanly incised, three-fourths of an inch in length, an inch and a half to the left of the median line, and nearly opposite the cricoid cartilage. This side of the neck presented a large tumor, due to escaped blood beneath. No bleeding followed the removal of the pressure, the clot being forced into and separating the edges of the wound. It was quite evident that one of the large vessels had been injured. It was not deemed expedient to give an anæsthetic, as there were no hands to spare for that. An incision was promptly carried through the skin, beginning an inch and a half above the wound, intersecting its outer end, and downward toward the sternum. The deeper tissues being divided, the clot was forced out, and a terrible hemorrhage ensued, which was checked for the time by hastily crowding sponges into the incision. It was noticed that both arterial and venous blood gushed from the wound. Maintaining the pressure on the sponges, I directed Dr. Deane to carry the incision completely down to the sternum. It was then found that the sterno-mastoid had been divided by the chip of steel through nearly three-fourths of its substance, which fact facilitated the search. Pushing the muscle back, we discovered that the internal jugular had been completely severed. We had found the proximal end, and it was immediately ligated. Removing the sponges *en masse*, and guided by my fingers, I hastily applied through the current of blood four artery clamps, and upon the application of the fourth saw the bleeding suddenly cease, whether from death or the seizure of the artery I could not at first say, for I had noticed a deathly pallor spread over the countenance. Just then, however, the man opened his eyes, and a gush of venous blood from above indicated that there was still life. Pressure being applied above, over the jugular, I cleansed the wound, and found on the common carotid, between the third and fourth pairs of forceps, at a point just below the cricoid cartilage, an opening in the artery involving fully one-half its calibre. So admirably had the forceps been applied that no readjustment was necessary. The sheath was dissected from the vessel with a bent director, and braided silk ligatures were applied by means of a curved fenestrated probe. Our attention was next directed to the distal end of the jugular vein, which we reached by splitting up the sterno-mastoid muscle, and then ligated. The missile had penetrated to the transverse processes of the cervical vertebræ, its course evidently having been arrested by the same. The hemorrhage was checked, but our patient's condition was not a flattering one, for he was pulseless at the wrists, and the surface was covered with a cold perspiration. He was conscious, however, and told me that he had not lost consciousness throughout the operation, though I thought at one time he was in a fatal syncope. Whiskey and milk were now freely administered, the wound was thoroughly cleansed with a 1 to 2,000 sublimate solution, freely powdered with iodoform, and the edges were brought together with silk sutures, except in the middle, where the ligatures, four in number, were brought out. Iodoform gauze, borated cotton, paraffine paper, and a bandage completed the dressing. An hour later he was taken on a stretcher, the head depressed, to a house near by and placed in bed, the foot of which was raised. Bottles of hot water were placed about, and blankets over him, whiskey and milk were given as often as he would swallow, one-fourth grain of morphine was administered hypodermatically, and the patient was strictly enjoined not to attempt to stir, speak, or have anyone but the attendant in the room. There was then some slight indication of radial pulse.

At midnight the pulse was 92, and the patient was quiet; another one-fourth grain of morphine was administered as before. He had taken the whiskey and milk well. Dr. Deane remained through the night, and was obliged to repeat the morphine once.

For the next two days the temperature ranged from 100° to 102°, and the pulse from 84 to 100. At the end of this time the patient began to complain of inability to move the right arm and leg, and I now found complete paralysis of motion, and also of loss sensation, on the right side. No paralysis of the tongue or facial muscles. This paralysis probably took place at the time of the ligation, but was not earlier observed, as I had so strictly insisted on perfect quiet. His voice was also husky, and he could not speak above a whisper. This he noticed immediately after the receipt of the injury, and it suggested some lesion of the recurrent laryngeal nerve. Dr. Deane suggested acute cerebral anæmia as the cause of the hemiplegia, and the subsequent history of the case proved this to be the most probable cause.

On the fifth day the patient had a rise of temperature and became delirious. A small pocket of pus which was found in the upper angle of the wound was emptied and washed out, and the fever and delirium soon disappeared. The ligatures of the carotid artery came away on the 16th and 18th of June, and those of the jugular vein on the 21st and 22d. From this time the improvement continued, and the patient resumed work on October 10th, and has worked steadily since that time, though his voice is still husky and he is not as strong as he was before the accident.

INTUBATION OF THE LARYNX—ASPHYXIA FROM OBSTRUCTED TUBE.

By W. C. DEMING, M.D.,

ASSISTANT PHYSICIAN, STATE EMIGRANT HOSPITAL, WARD'S ISLAND.

Antonina Dorsa, aged two, born in Italy, was treated for pneumonia in the New York State Emigrant Hospital, last February and March, and recovered. She remained here till the latter part of April, regaining strength slowly, when she was taken sick again with symptoms of pneumonia and also increasing laryngeal obstruction. This became so marked about the second day that, on consultation with Dr. Marple, the acting physician-in-chief, it was thought best to intubate. Accordingly, this was done by Dr. Marple, with immediate and marked relief to the patient. The smallest tube was used. No false membrane could be seen.

Two days later, the tube having been worn continuously in the meantime, while the patient's chest was being examined she coughed, gagged, vomited a little coagulated milk, and suddenly ceased to breathe. The larynx was absolutely occluded, although the child made, for it, heroic efforts of inspiration. After a few seconds she was inverted and slapped on the back, and the chest was compressed in the hope of dislodging the tube. This did not succeed, but the nurse having meanwhile brought the extractor, which was at the other end of the ward, it was introduced and the tube was immediately withdrawn. The child was now unconscious, fearfully cyanosed, and had ceased to make any efforts to breathe, but after a few minutes of artificial respiration, we had the pleasure of seeing a return of consciousness, and breathing again beginning. The laryngeal obstruction was still so marked, however, that, after about fifteen minutes, the tube was replaced, with the same relief resulting as at the first introduction.

On examining the tube a small amount of soft, white matter, probably coagulated milk, was found in it, but not apparently occluding it. A small piece of what might have been false membrane was found somewhere about the instrument, but not in the tube.

The child died in a day or two, with extension of the pneumonia, the tube being left in till death. On autopsy, by Dr. Thacher, there was found pneumonia in both lungs, and "deep ulcers in both tonsils, ulcer on epiglottis [perhaps traumatic], inflammation of larynx and trachea with exudation, apparently fibrinous, and some loss of epithelium." The exudation was, however, very thin.

Was the occlusion caused by the milk, by the small membrane-like particle, which might have been detached from the upper opening of the tube by the extractor, or by membrane from below, which did not come away with the tube?

Probably the tube was not coughed out because the stoppage took place at a moment of extreme expiration following the vomiting.

FATAL OBSTRUCTION OF THE BOWELS WITH PECULIAR FEATURES.

By R. R. LAWRENCE, M.D.,

HARTFORD, MICH.

On Sunday, November 6, 1887, I was called to visit Mrs. A——, widow, sixty-one years of age, a well-preserved lady of full habit, and with a history of good health quite remarkable for one of her age, preceding the commencement of the present trouble. The pulse was from 102 to 108; temperature normal. Subjective symptoms were negative, save an increased tendency to constipation dating back about eighteen months, during which time, at frequent intervals, she would take a cathartic followed by temporary relief. It was sometimes necessary to repeat the cathartic before an evacuation of the bowels could be obtained. Objective symptoms were negative, except the acceleration of pulse. I was called in consequence of the usual remedies having failed, and ordered laxatives, with no result. Cathartics supposed to be more thorough were then tried, but in vain; finally the drastics, viz., elaterium, oleum, tiglium, etc., favored by enemas, with disappointment in every instance. By this time there was great distention of abdomen occasioned by flatus, with very loud borborygmi, which could be distinctly heard in a room quite distant from the one occupied by the patient. Diagnosis: Intra-intestinal tumor, of the nature of which I had no idea. Its location was also uncertain, but, as a copious enema could not be given, I inferred it was low down. Paroxysms of pain, produced by flatulence, were frequent and excruciating in character, requiring morphia hypodermatically, as the stomach was irritable. Nourishment was taken very sparingly, and consisted wholly of liquids. Case progressed without any notable change until December 25th, when there was stercoraceous vomiting lasting several hours, after which the patient could be persuaded to partake of but little food. During her entire illness there was *no evacuation of the bowels*, the enemas being merely tinged with the secretions of the rectum. The thermometer never registered any elevation of temperature, and after the first three weeks the pulse did not deviate from 120 per minute.

Death occurred at 2.20 A.M., January 10, 1888—sixty-five days after the patient had taken to the bed. Autopsy twelve hours after death: Rigor mortis absent; slight emaciation. Intestines greatly distended, especially the colon, the muscular coating of the latter being thickened and imparting a leathery sensation to the touch, the whole tract containing a yellowish-colored fluid, resembling in consistence and appearance *egg nog*. Abdominal organs normal. Tumor located in the sigmoid flexure of the colon, cystic in nature, containing the same characteristic fluid, interspersed with a gelatinous substance. The sigmoid flexure was distended to its utmost capacity; in fact, the tumor filled the entire space. At the junction of the colon and rectum the tube was attenuated to a mere cord, and surrounding that part which should have been the opening was a calcareous deposit of the hardness of bone, resembling it in many respects, and, the most startling of all, *a tuft of hair* (perhaps a nucleus), some of which was three or four inches in length, of a yellowish-white color, the whole forming a mass which, if globular in form, would have been about the size of an average English walnut. This case possessed many peculiar features, as rapid pulse without febrile movement or nervous symptoms; the absence of all inflammatory action; length of time bowels remained in a quiescent state; the mode of death, being evidently gradual failure of the heart's action. Will some one of the many readers of The Medical Record inform me how hair became a part of the contents of the cyst, and whether its formation preceded the calcareous degeneration, or *vice versa?*

ANTIFEBRIN AS A HYPNOTIC.

By J. B. KELL,

DELPHOS, O.

In the issue of The Record of December 17th, I notice an article by Dr. G. Dalton Hay upon the use of antifebrin and antipyrin as hypnotics. While never having had experience with the remedies in any case without a certain degree of pyrexia being present, yet so marked was the effect in the reduction of temperature, delirium, and relief from an insomnia almost absolute, that I wish to record the action of antifebrin in the treatment of a disease in which delirium of a violent form and insomnia are, as a rule, almost constantly present. I refer to acute alcoholism. The case was one in which a man, aged twenty-seven, had indulged in a protracted spree. He was of a neurotic temperament, and inclined to a condition, upon retiring for the night, which he termed "unstrung." After the fourth day had been spent in a constant round of dissipation, he was taken to his home by friends and put in bed. As evening came on his delirium assumed a violent form, manifesting itself in his attempts to strangle his attendants, who were required to hold him in his bed. When called, I found him with all the marked symptoms of a well-defined case of acute alcoholism. The increase of temperature was slight (101.5°); pulse, 85; skin, of a cold, clammy "touch." He was given potassii bromidum and chloral hydrate, grs. xv., every four hours, for the purpose of inducing sleep. He also received quinia sulph., grs. xx., for reduction of temperature, which was almost immediate, but without cessation of delirium or relief of insomnia. The next morning I was informed that his night had been one of constant wakefulness and movement. I now put him on opii pul., grs. iij., every two hours, but effect was negative.

Toward the evening of his second day in bed his condition became alarming; his pulse was now 140, and dicrotism marked; temperature, 103°; low muttering delirium and subsultus tendinum. I now suspended the use of all other remedies, and administered antifebrin in doses of ten grains. After the second dose had been given the patient passed into a sleep, at first interrupted by involuntary muscular contractures. These, however, soon passed away, and under the influence of a third dose the sleep became profound. The temperature was now reduced to 99.5°, while the circulation had become much stronger (112), with an absence of the dicrotic character. After a period of five hours' rest he awoke, but almost immediately was given a fourth dose, of grs. viij., which prolonged the rest four hours. In conjunction with supporting measures the use of antifebrin was continued to convalescence, which was prompt and satisfactory.

Applying ourselves to the case under consideration, it appears that antifebrin is directly an antipyretic and a hypnotic, and not, as one would suppose, directly an antipyretic and indirectly a hypnotic; or, in other words, the latter therapeutic effect depending upon the former, for the reason that, in this case, prior to the use of antifebrin, quinia was given in antipyretic doses, with a consequent reduction of heat but no cessation of delirium or insomnia; in fact, I may add, they appeared to be aggravated. While under the influence of antifebrin, not only was an absolute reduction of heat accomplished but its effect as a cerebral sedative and hypnotic was well marked. It is true that the absence of delirium and production of sleep, under the use of the alkaloid, may be due to the accompanying reduction of temperature; but, if this be true, why not secure the same effect from antipyretic doses of quinia and the cold bath, both of which failed utterly in this case?

I have noticed in several of my journals articles upon the use of this remedy for the relief of that functional disease, insomnia, but as yet I have not seen it recommended in the treatment of acute alcoholism. It is well recognized that in the grave forms of delirium tremens, associated with or without surgical injury, the more common soporifics and hypnotics will fail to produce the desired effect, and if we can secure a remedy which meets the indications so successfully as antifebrin seems to have done in this case, this one value in itself will amply repay all time spent in its investigation. Of course, *one* case is, in one sense, unimportant; what is needed is a *collection of cases*, from which deductions can be drawn, thus reducing its study to a working level.

A CASE OF CHRONIC MEMBRANOUS ENTERITIS, WITH PERIODICAL EXACERBATIONS.

By H. S. KILBOURNE, M.D.,

ASSISTANT SURGEON, UNITED STATES ARMY, PORTLAND, ORE.

I. X——, aged fifty, married, tall, spare, of nervous temperament, came under observation in October, 1886, with the following history: The patient had been in active service, during the war, in North Carolina and other malarious districts, where he had contracted intermittent fever, from which he suffered severely at intervals for years.

In 1882–83, while serving on the plains, he had recurring attacks of "colic," which were attributed to occasional indiscretions in diet. In 1883 he first observed that some of the discharges from the bowels contained patches and shreds, having a membraniferous appearance. These were more abundant after the attacks of "colic." From 1883 until the present time he has had numerous exacerbations of his malady, and during this time he has never, excepting for short intervals, been altogether free from the characteristic discharges. In May, 1886, when I first saw him, he was under the care of an associate, and recovering from an illness of several weeks' duration, which was characterized by great debility and prostration. When I took charge of the case, in October, 1886, he was in bed, suffering from pains of moderate intensity, radiating from the umbilical to the right iliac and hypochondriac regions, with slight tympanites. The pulse was 100; temperature, 99°; and there was a degree of mental and nervous irritation amounting to hypochondria.

The pain was mitigated by hot fomentations and anodynes, and was followed on the second day by a copious discharge of mucous casts from the bowels, after which there was relief of the symptoms.

On examination of the casts they were found to consist of ribbons, patches, and shreds of white pseudomembrane, having a resemblance to the patches detached from the fauces in cases of diphtheria. They were grayish white, smooth, varying in thickness from that of tissue-paper to blotting-paper. There were ribbons from one-half to one inch wide to two feet in length, some being rolled up like cocoons, others coiled up in masses which readily unfolded when floated in water. Other specimens were shreds and patches of varying sizes and forms. Examined by the microscope, no traces of organization were found. When tested with reagents they did not give the reactions of albumen or fibrin, but seemed to be mucous in character.

The quantity discharged varies from a mere trace to an ounce or more, with each discharge, and since my observation began there have been but few discharges that have been free from mucous. Occasionally, after a paroxysm, in addition to the casts, there will be found mingled with them masses of a gelatinous, amber-colored exudate, in quantity amounting to one or two fluid ounces. The present condition of the patient appears to be that of profound anæmia. The skin has an icteroid hue, the patient is emaciated—especially in the lower extremities—the tongue is pale, large, and constantly coated with white fur, which occasionally has a tinge of yellow in the median line. There is at times slight œdema of the lower extremities, and of the eyelids and face. The bowels are habitually constipated, but are easily moved with two or three grains of calomel, or by enemas of warm water. The appetite is variable, with anorexia during the exacerbations. The mind is clear, but easily disturbed. The patient is constantly disturbed by a hæmic murmur in the cervical blood-vessels. The pulse-rate, during the exacerbations, which continue from two to ten days, rises to about 100, and gradually returns to an average of about 80. Palpitation and cardiac intermissions occur frequently. Valvular disease, with a compensatory hypertrophy, has been suspected, but not accurately determined. The border of the liver does not appear below the ribs. The spleen is not perceptibly enlarged. The urine is clear, abundant, and free from albumen and glucose. The patient sleeps fairly well, and without the assistance of anodynes, excepting at the culmination of his attack. The fæces, when brought away by a laxative or enema, are frequently composed of hardened masses of the size of marbles—not unlike the droppings of sheep—in which case the color is darker than usual. The distinctive feature in the complexus of symptoms present in this case appears to be the condition of the intestines, which, however, has not within my observation presented the evidences of an acute inflammatory process. During the height of the exacerbations, there is but very slight tenderness on pressure about the abdomen.

The disease is non-febrile; the temperature is more frequently sub-normal than otherwise. The hydremia appears to be the result of failure of the powers of assimilation.

During the past summer the patient improved markedly in his general health; his flesh and strength returned, and no paroxysms have occurred. Nevertheless, occasional casts have been discharged, showing that the disorder, though latent, still exists.

ANTIPYRIN IN ACUTE AND PAINFUL EYE AFFECTIONS.

Dr. B. J. Wetherby, Arlington, Kan., reports the following case: "Mrs. O——, aged about forty, married, came to me, January 1, 1888, for treatment for what she termed 'a sore eye.' On examination I found intense conjunctivitis of the right eye, with considerable trachoma. There was intense photophobia and lachrymation; and the patient stated that every day, at irregular hours, pain would begin in the eye and extend from there to the head and neck, gradually becoming so intense that she was obliged to go to bed. The pain always became greater toward evening, and was so severe as to prevent her sleeping until near morning. The patient assured me that this state of things had persisted for over a month, and that she had not had a continuous night's sleep in that time. I immediately began the usual treatment, with the result of precipitating the attack of headache as well as of prolonging it, and this same unhappy result was produced three times. At this time I noticed Professor Ryerson's article in The Medical Record on the use of 'Antipyrin in Acute and Painful Affections of the Eye,' and resolved to try this remedy. Accordingly I gave my patient six powders, of fifteen grains each, instructing her to take one on going home and immediately to lie down—the powder to be repeated in two hours if necessary. She did as directed, and found no need to use a second powder. The effect was 'almost magical,' and at eight o'clock the patient went to sleep and slept soundly till the next morning, when she awoke feeling better, as she expressed it, than she had for weeks. She took one powder after each of the two following applications, with the same happy result; and since then she says she has been entirely free from pain, except a transient smarting following each application to the lids. I think the antipyrin had a controlling action on the inflammation, since the eye has improved more rapidly than any other eye I ever treated which was similarly affected."

A CASE OF TYPHOID FEVER WITH SOME PECULIAR FEATURES.

Dr. L. B. Dawley, of Binghamton, N. Y., writes: "The following case presents some unusual features which, I think, render it of sufficient interest to justify this report. The patient was a lad, seven years of age, in whom all the prodromal symptoms of typhoid fever were developed in the usual way. The temperature rose rapidly, and attained a height of 108° F., at which point it remained for two weeks, with at no time a reduction of to exceed one degree. At the end of the second week pneumonia developed, and subcrepitant râles were heard over both lungs. At the beginning of the third week complete aphonia took place, and he was unable to articulate a single word. During the remaining time of the fever, which lasted twenty-one days in all, and for three weeks of convalescence, he did not speak a word. After the application of electricity and under the stimulus of constant encouragement he spoke the word 'ma.' He learned to speak as the child does, only it came to him more rapidly. It seemed difficult for him to get the sound of the vowels. Another feature of the case, and it may seem incredible, was the large amount of nourishment taken. From the development of the fever milk and beef-tea were given, and in the second week he had raw eggs in his milk. He had one and one-half pound of the round of the beef made into tea in the most approved way. This amount of beef-tea and two quarts of milk were taken by him each twenty-four hours, and in the second week, in connection with the above, he took a fresh egg beaten in a glass of milk four times a day. Never for one moment did the stomach go back on this regimen.

"I never saw a more severe case that recovered. The two characteristic features of the case were the complete loss of voice and the large amount of nourishment taken. The patient never lost his reason or his hearing. When asked a question, to be answered by yes or no, he would raise his hand or not, as requested.

"I do not think that typhoid fever is of as frequent occurrence in children under eight years of age as it is in adults. I am fully convinced in my own mind that the disease is not contagious, but that it comes from decaying matter, either animal or vegetable. The house in which this patient lived had previously been occupied by people who evidently did not believe that 'cleanliness is next to godliness.' The present incumbents have had the premises thoroughly renovated, and I think the disease can be attributed to the filth. After an experience of nine years I have come to the conclusion that it is almost impossible to abort the disease, at least as late as the beginning of the second week, whatever plan of treatment may be adopted."

THE TREATMENT OF DIPHTHERIA.

Dr. F. J. T. Fisher, of Elmhurst, Ill., writes: "I have read with much pleasure Dr. Baruch's 'Therapeutic Memoranda on Diphtheria,' in your issue of December 24, 1887. I have now, for several years, pursued substantially the same treatment. I add, however, a little chlorate of potash to the tincture of iron solution, and I dissolve the corrosive sublimate in a little muriatic acid, and add this directly to the above, making only one solution instead of two; and then I order a teaspoonful of this solution to be taken every half-hour, instead of every hour, as Dr. Baruch directs. In the twenty-four hours my patients get about the same quantity that Dr. Baruch prescribes—my solution being only half as strong as his.

"To adults, however, I have, in severe cases, given in the twenty-four hours as much as one and one-fourth grain of the corrosive sublimate, instead of three-fourths of a grain, the quantity apparently not exceeded by Dr. Baruch. Of the turpentine I give about the same quantity, but instead of one I give it in three doses. When the turpentine is given the other medicine is for two hours discontinued.

"It is very rarely the case that I have to stop either the corrosive sublimate or the turpentine. I have treated between forty and sixty cases in this way, with comparatively few deaths, and these few may in great part be fairly attributed to their not receiving treatment soon enough. The diphtheritic membrane is by these means usually dissolved in from four to seven days.

"If Dr. Baruch's article had been written ten years ago, it would have saved me a great deal of worry and anxiety."

PROTECTING THE PERINEUM.

Dr. W. V. M. Taylor, of M'Keesport, Pa., sends the following communication: "I find, in looking over the literature of the past few years, much written on the subject of operation for lacerated perineum, but very little concerning the prevention of this accident. Up to within the past few years I believed that rupture of the perineum was of almost necessary occurrence in primiparæ, and no methods of supporting the perineum seemed to be of any use in preventing the accident. I do not support the perineum, in the sense of making forcible pressure against it and the advancing head, but I endeavor to prevent laceration by placing the thumb and forefinger, and, in some cases, the points of all the fingers behind the anus, at or near the tip of the coccyx, and pressing against the brow of the child, pushing it toward the pubes. The other hand supports the head in order to prevent its too rapid descent. The advantages of this method are: 1. The accoucheur has complete control of the labor, and there is no possibility of injury to the mother or child. 2. By maintaining the perineum on a gentle continuous tension, dilatation is much more easily effected than when there is an alternation of extreme tension and complete relaxation. 3. This is the only direct way of helping the uterus, 'pushing around a corner,' as Dr. Landis expresses it. 4. By being doubled upon itself from behind forward the perineum is rendered more elastic. 5. This is a very great assistance in forceps-operations. The head is steadied with the forceps held in the left hand, and, when the perineum is well on the stretch, the brow is to be caught with the fingers of the other hand in the manner described, and the head is then pushed out with as much safety to the integrity of the perineum as in an ordinary labor. These are great advantages over the method with the finger in the rectum. I would earnestly ask the profession to give this method a fair trial, feeling that the results obtained will be most gratifying."

A CASE OF SUPERFECUNDATION.

Dr. R. T. Edwards, of Vicksburg, Miss., writes: "In your issue of January 7th, there is a report from the *Medical and Surgical Reporter* of 'Twins; one Black, and one White,' by Dr. Newton Hill, of Pickensville, Ala. A similar case occurred in this State that was explained by the mother to an inquiring physician. She had been separated for a month or more from her husband, a black man. While she was engaged in picking cotton one day, a young white man approached her in the cotton-field, and she yielded to his requests and they held sexual congress. That night her husband returned, a reconciliation followed, and she submitted to *his* rights as husband. Nine months afterward she was delivered of twins, one black and one white."

TWO CASES OF FOREIGN BODIES.

Dr. E. J. Jones, of Oak Hill, O., reports the following cases: "Mr. J——, being fond of shooting squirrels, one day made several dozen rifle-balls and placed them in a small box where he usually kept them. After eating his dinner, he was preparing to go to look for squirrels, but the rifle-balls could not be found in the box. After searching in vain for the balls he abandoned his purpose. The following day his three-year-old boy passed, with the fecal evacuations, forty-two rifle-balls. The child had shown no signs of sickness.

"The following case also occurred in the same neighborhood. A two-year-old girl had been noticed picking at the nose (which was slightly swollen) for several days. One day she forcibly sneezed, ejecting from the nostril a large white bean, which had growing from it a young sprout about half an inch long. The bean had undoubtedly sprouted in the nostril, as there were no sprouted beans about the house."

Pure Terebene in the Treatment of the Advanced Stage of Uterine Cancer.—Attention has been called to the value of pure terebene in the treatment of advanced cases of cancer of the uterus. The vagina is first injected with a small quantity of a strong disinfecting solution (permanganate of potash or chlorine water), and washed out with a copious supply of tepid water. Then plugs of cotton-wool, saturated with a mixture of equal parts of terebene and olive or almond oil, are placed in contact with the ulcerated surfaces, and maintained in apposition with a large plug of wool. This dressing only needs to be removed every second or third day. If care be taken not to make the plugs too voluminous, no inconvenience will be felt from their pressure.—*The Medical Press*, December 7, 1887.

Œdema of the New-born and Phlegmasia Alba Dolens.—At a recent meeting of the Academy of Medicine of Paris, Dr. Dumas spoke upon the probable identity of œdema of the new-born and phlegmasia alba dolens. He thought the former should not be confounded with sclerema, for it is characterized by the infiltration of serum into the subcutaneous cellular tissue and into all the cellular interstices of the affected parts. On the contrary, this œdema should be regarded as a symptom of phlegmasia. Treatment should consist in the employment of heat in the form of the *couveuse* of Tarnier. He warns against manipulation of the affected parts, still recommended by many, as it tends to the formation of emboli.—*Le Progrès Médical.*

Army News.

Official List of Changes in the Stations and Duties of Officers serving in the Medical Department, United States Army, from February 5 to February 11, 1888.

JANEWAY, JOHN H., Major and Surgeon. Detailed as member of the Army Retiring Board in San Francisco, Cal., convened by S. O. 168, A. G. O., July 22, 1886. S. O. 28, A. G. O., February 4, 1888.

HOPKINS, WILLIAM E., Captain and Assistant Surgeon. Detailed as member of the Army Retiring Board in San Francisco, Cal., convened by S. O. 168, A. G. O., July 22, 1886. S. O. 28, A. G. O., February 4, 1888.

JARVIS, NATHAN S., First Lieutenant and Assistant Surgeon. Ordered from Fort Lewis, Col., to Fort Leavenworth, Kan. S. O. 30, A. G. O., February 7, 1888.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 11, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	1
Scarlet fever	161	24
Cerebro-spinal meningitis	1	1
Measles	47	5
Diphtheria	183	55
Small-pox	7	1
Yellow fever	0	0
Cholera	0	0

PHTHISIS CAUSED BY A HYPODERMIC NEEDLE.—Erlenmeyer, in his work on the opium habit, records a case in which fatal tubercular poisoning was believed to have been produced by the hypodermic needle. A physician, aged thirty-eight, who had been accustomed to use the same needle for himself and a tuberculous patient, died suddenly, and at the autopsy a tuberculosis, strictly localized to the peritoneum, was found.

THE RELATION OF CONVULSIONS TO ARTERIAL TENSION.—In his Croonian Lectures Dr. Broadbent observed that convulsions were sometimes associated with increased arterial tension, and suggested that uræmic convulsions were largely due to the high tension. In support of this he adduced the fact that blood-letting has often a remarkable effect in cutting such convulsions short. Dr. Ringer has propounded a theory of at least equal plausibility to account for this effect of blood-letting, namely, that by suddenly reducing the bulk of fluid in the vascular system, it leads to a rapid flow of watery fluid from the tissues to restore the balance, and that the beneficial effect is due to this dilution of the poisonous matter in the blood. However this may be, we ought not to lose sight of Dr. Broadbent's other observation, that ordinary epilepsy is usually associated with low arterial tension.—*British Medical Journal.*

THERAPEUTICS OF CHRONIC ARTICULAR RHEUMATISM.—At the Sixtieth Congress of German Naturalists and Physicians, at Wiesbaden, Ziemssen read a paper on this subject, in which he made the following points: 1. Chronic articular rheumatism is a general disease; though at times it may be quite localized, yet there exists no surety that the disease may not again become general. 2. Therefore treatment must at the outset be general. 3. The disease is often so inveterate at special points that a combined local and general treatment is necessary. 4. In the affected joints are almost always found separate spots with a distinct border, which can be accurately marked out by touch and by the sensation of pain on the part of the patient. 5. The pain is often complicated in such a way that either the diagnosis is doubtful, as in arthritis, syphilis, gonorrhœa, and after injury; or that the pains belong to another kind of rheumatism, for example, muscular rheumatism, rheumatic neuralgia, sciatica, and heart-disease. 6. Such complications are to be dealt with at the same time with the general disease. 7. Treatment is not to cease before complete cure is obtained, otherwise a relapse would not be surprising. The rheumatic diathesis itself is the uncured disease. Treatment is general and local. General treatment consists in the regulation of nutrition, in an out-door life, in promoting increased activity of the skin, in the use of warm and hot baths, in wearing woollen clothing, and a regulation of the whole style of living; and finally, in large doses of salicylate of soda. This remedy is, when rightly used, very well borne, has no contraindications, and acts so specifically that when failure results from its use an error in diagnosis is to be inferred. The local treatment, which is to be employed simultaneously with the general treatment, consists in the use of massage, combined with warm douches while the patient is in a warm bath. By means of tubing and a bellows, a stream of water, under a pressure of three to seven atmospheres, is projected against the affected part, which at the same time is manipulated by a skilled attendant. This treatment excels all other local measures. In other rheumatic affections, such as muscular rheumatism and sciatica, this method of treatment by douche is very efficient.—*Medical and Surgical Reporter*, December 3, 1887.

THE FREQUENCY OF STERILITY IN THE MALE.—According to Kehrer, the cause of childlessness in many marriages is to be sought much oftener on the side of the man than has heretofore been the custom. This statement is based upon an investigation of the semen. Kehrer has, up to the present time, instituted this investigation in ninety-six cases. In 3.12 per cent. there existed inability to copulate; in such cases there had always been preceding masturbation. The men suffered from frequent pollutions, or the ejaculations were premature, so that the penis was not inserted into the vagina. In these cases impregnation may result, if before the attempt at coitus a speculum be introduced into the vagina. In several cases conception was obtained by this manœuvre. In 31.21 per cent. azoöspermia existed. In most of these cases gonorrhœa, with unilateral or bilateral orchitis, had preceded. The author lays particular stress upon occlusion of the ejaculatory duct through gonorrhœal prostatitis. But azoöspermia was also found where no disease of the sexual organs had occurred, and where nothing abnormal in the genital organs could be demonstrated. Oligospermia was demonstrated in 11.45 per cent. Several times masturbation was confessed, or else gonorrhœa with orchitis, or syphilis, had preceded. But, in addition, the author thinks that the diseases of the female sexual apparatus which may condition sterility are considered too numerous. Principally, catarrhs under certain circumstances lead to sterility, and Kehrer also thinks that bacteria may exert a destructive influence upon the ovules. It is a question whether these bacteria produce inflammation of the mucous membrane, or only find in the latter suitable conditions for further development.—*The Medical and Surgical Reporter*, December 10, 1887.

STRYCHNIA AS A HEART STIMULANT.—In "St. Bartholomew's Hospital Reports," Dr. Habershon writes on the use of strychnia by hypodermic injections in cases of heart failure. In this paper Dr. Habershon discusses the *modus operandi* and effects of various heart tonics, such as digitalis, alcohol, ether, and ammonia, and concludes that none of them are so useful as strychnia in cases in which not only the heart-muscle, but also the nerves which promote and control its activity are exhausted. The order of excellence seems to be digitalis for a prolonged effect ; and ammonia, or ether and alcohol, for a more rapid but less lasting one. It is somewhat surprising to find the statement that Dr. Habershon has never found ammonia "to act where brandy and ether have not succeeded." This sentence is not easy to analyze, but we incline to the opinion that if ammonia be used by intravenous injection, it will be found capable of arousing the vaso motor and respiratory centres to a temporary activity when nothing else will. The principal value of Dr. Habershon's paper is in calling attention to the influence on the heart by hypodermic injections of from $\frac{1}{60}$ to $\frac{1}{30}$ of a grain of strychnia. He cites cases of disease of the mitral and aortic valve, and of pneumonia which had advanced to a state of cyanosis, with weak and rapid pulse, and hurried or Cheyne-Stokes respiration, in which the use of strychnia seemed to cause the tide of life to turn back, and recovery ultimately took place. These cases may be regarded as establishing the opinion which he has formed of the great benefit to be derived from the hypodermic use of this drug in conditions of exhausted heart-muscle, accompanied by exhaustion of the nerves which supply the heart. Dr. Habershon suggests that the most convenient solution of strychnia for hypodermic use consists of one grain in fifty minims of water. We would suggest that it would probably be easier to regulate the dose if the solution were only about half as strong as this, consisting of one grain of strychnia to one hundred and twenty minims (two fluid drachms) of water. Two minims of such a solution would contain $\frac{1}{60}$ of a grain of strychnia, and four minims $\frac{1}{30}$ of a grain.—*The Medical and Surgical Reporter*, December 10, 1887.

Penetrating Wounds of the Gravid Uterus.—At the Société de Chirurgie M. Schwartz read a paper on penetrating wound of the gravid uterus. A young woman, aged twenty-two, *enceinte* six months, received a stab of a knife in the abdomen. The intestines protruded through the wound as well as the two feet of the fœtus, and a quantity of blood was lost. However, as the condition of the patient was pretty fair, M. Schwartz decided on interfering. The wound in the uterus was enlarged and a dead fœtus was removed. The incision was sutured and antiseptic dressing applied. On the third day peritonitis set in, and death took place a few hours subsequently. The author asked his colleagues what other line of conduct should he have followed? M. Berger replied that there were several kinds of uterine wounds. He cited one case in which the patient made a good recovery. M. Guéniot was of opinion that the operation should be made as quickly as possible in such cases. Transverse wounds unite much more quickly than longitudinal. In the Cæsarean section the incision is generally, if not always, longitudinal, but it would be much preferable to make it transverse. M. Marchaud thought that Porro's operation was the best.—*The Medical Press.*

Non union of Bone during Pregnancy.—M. Padieu, of Amiens, describes the case of a woman who fractured the tibia and fibula of one leg on January 4, 1886. The fracture was put up in a many-tailed bandage. At the end of a month it was found that there was still movement between the fragments, and a fortnight later there was no further progress. At the end of three months and a half, M. Padieu put the patient on crutches in order to hasten consolidation. Union was still delayed ; then he began to suspect pregnancy. The patient admitted that her period had not recurred since December 26th, nine days before the accident. The abdomen and pelvis were examined, and M. Padieu's suspicions were confirmed. Delivery occurred on September 28th, and a well-nourished live child was born. Ten days after delivery the patient noticed that her leg felt much stronger than it had ever been since the accident. At the end of a month union was perfect. The *Archives de Tocologie* observes that this case was remarkably clear and authentic. The physiologist and obstetrician may advantageously consider the facts of the case. The delay in ossification of the callus must surely be due to some cause more subtle than mere debility. Indeed, the amount of debility involved in an average pregnancy is often very trifling. Severe abdominal operations, even double ovariotomy, have been tolerated with impunity during gestation, the wounds healing and delivery occurring at term. The theory that lime-salts are used up during pregnancy for the benefit of the fœtus, and to the prejudice of the callus, will hardly bear strict examination, or at least it demands strong proof that local nutrition in the parent is palpably affected.—*Maryland Medical Journal.*

The Etiology of Typhoid Fever.—Dr. Quine's views on typhoid fever are summarized by the *Philadelphia Medical Times* as follows : 1. The exciting cause is a specific, poisonous, microscopical germ ; and under no circumstances can typhoid fever originate from the influence of filth alone, unless that filth contains the specific germ. 2. The germ is practically immortal. Typhoid dejecta may be imprisoned in an old cesspool or unused sewer-pipe for half a century, and then, after a lapse of this period, when this cesspool or unused sewer-pipe is opened, the typhoid germ literally springs into existence with frightful malignancy, and a few whiffs from the accumulations in the cesspool will be sufficient to cause it. The germ does not die spontaneously ; it can be killed. 3. The germ multiplies in the human body, and an inconceivably minute quantity of this germ introduced into the human system makes the individual susceptible to the disease. An individual having a dozen movements of the bowels a day, each dejection contains germs enough to impart it to a hundred or thousand individuals ; so there is clear proof that the germ multiplies in the human body. 4. The specific germ of typhoid fever is eliminated by the bowels. A person may inhale the breath of a typhoid patient without danger of contracting the malady. He may lie on the same bed throughout the entire course of the disease without danger to himself, unless in some way the intestinal dejections or emanations have found their way into his own circulation. The poison is not contained in the urine, nor in the emanations from the surface of the body, but simply in the fæcal discharges. 5. The fresh germ itself is innocuous—non-poisonous. Some investigators in Germany have engaged in the unpleasantry of drinking down fresh typhoid discharges, and have demonstrated with absolute certainty that these fresh discharges are innocuous. 6. In order for the discharges to acquire activity or virulency, they must be exposed to atmospheric air ; hence old typhoid putrid discharges undergo partial decomposition. 7. The poison of typhoid fever is almost invariably swallowed in drinking from impregnated water-supplies. It is sometimes swallowed in the food. In rare, exceptional cases, typhoid germs may be diffused through the atmosphere, and find their way into the human body through the lungs. 8. A patient may have the disease two or three times ; one attack does not protect him from subsequent attacks.

Simplified Antisepsis in Obstetrics.—Dr. W. Bolselmann, of Berlin, has formulated the following propositions for the guidance of obstetricians. It will be observed that his chief aim is to do away with the unnecessarily cumbersome antiseptic apparatus of some authors and to substitute therefor simple and yet efficient measures for the prevention of infection. It is to be remembered, in the first place, that the healthy puerpera is aseptic. The danger of infection comes to her from without.

There being no infectious material in her genital tract, the latter requires no disinfection ; for there can be no disinfection in the absence of infectious material. The hands and instruments of the accoucheur are probable sources of infection. These must, therefore, be thoroughly disinfected before coming in contact with the woman's genital tract. In order to avoid introducing infectious material which may adhere to the body of the patient, the external organs must be thoroughly cleansed with soap and water, and then washed with an antiseptic solution. The vaginal canal should also be washed out once with an antiseptic solution before an examination is made. The most practical disinfectants are, solution of mercuric bichloride, 1–5,000, for the hands of the accoucheur and the genitals of the patient ; and a three per cent. solution of carbolic acid for instruments. No unnecessary examinations of the patient's genital tract should be made. After the cleansing and antiseptic vaginal douche above mentioned, vaginal and uterine injections are needless, and often harmful, and should not be used unless there is evidence of septic infection, as manifested by fever or offensive discharge. Intra-uterine douches should not be practised unless there is evidence of the presence of infective material within the uterine cavity.—*Berliner Klinische Wochenschrift.*

THE QUESTION OF OPERATIVE INTERFERENCE IN HYDATID TUMORS.—A discussion on this subject was had at the last meeting of the London Clinical Society. *The Medical Press*, December 14, 1887, summarizes the outcome of the debate as follows: The general opinion was evidently in favor of withdrawing a portion of the contents by aspiration as a tentative measure, but experience varied greatly as to the result which might be hoped for from this procedure, in so far as a cure of the disease was concerned. Should the cyst refill, the best course is evidently to cut down upon it, and, by stitching or otherwise fixing it to the edges of the abdominal wound, secure adhesion and thus obviate the danger of any of the fluid escaping into the abdominal cavity. Within a few hours, or at most within a few days, the cyst can be opened and the cyst wall removed with comparative safety. Should an abscess have formed, some surgeons are of the opinion that it is preferable to empty it at once. Hydatid cysts are by no means rare, but few surgeons obtain a sufficient number of cases requiring operation to enable them to form a reliable opinion as to the relative merits of the several procedures. Dr. Broadbent alluded to a point of some practical importance, viz., that where the fluid was clear and not filled with daughter-cysts, recurrence was rare after simple aspiration, and *vice versa.*

THE TREATMENT OF INTESTINAL PERFORATION PRODUCED BY EXTERNAL INJURY.—At a recent meeting of the Société de Chirurgie, a long debate ensued on the treatment of perforation of the intestines produced by external wounds. Two opinions had their partisans. One was that when the penetration was fully diagnosed the abdomen should be opened, the intestine sought for, and the wound closed to prevent fæcal matter from escaping into the peritoneum ; while the other was in favor of systematic abstention. M. Reclus said he would be inclined to the latter, or conservative, treatment, although he would not deny that sometimes the most heroic method may be called for. The diagnosis of traumatic perforation is very difficult. The tissues of the abdominal wall divided by the instrument close up again, and it is impossible, or nearly so, to say what damage has been done to the internal viscera. Sometimes it has been observed that the knife, or ball, just struck between the folds and thus left the intestines untouched. Such cases have been observed in the proportion of four per cent. As to the immediate signs of perforation, they were obscure and often wanting, and generally it is only when peritonitis supervenes that the fact is discovered. In penetrating wounds of the stomach hæmatemesis may be observed, whereas hemorrhage from the intestines through the rectum is not often witnessed *au début.* In any case, penetration is not necessarily fatal when treated without operation. Statistics have shown that although great damage may be done the patient recovers, and the reason may be found in the fact that stercoral matter is not always present in the intestine, as frequently the person has not eaten for several hours. In conclusion, M. Reclus indicated the line of treatment he would follow in penetrating wounds of the intestine. The patient is placed in a position of absolute repose, the external wound washed by an antiseptic solution and hermetically sealed by iodoformized collodion ; the abdomen is covered with a good layer of cotton and firmly bandaged with a flannel roller, as after ovariotomy. Subcutaneous injections of a third of a grain of morphia are given, and feed the patient on exceedingly small quantities of milk, beef-tea, or wine ; thirst will be combated by ice in the mouth. If, in spite of all, peritonitis is observed, laparotomy remains the only resource.—*The Provincial Medical Journal*, January 2, 1888.

THE TREATMENT OF HEADACHES BY NITRO-GLYCERINE.—Dr. Trusevich has published a series of observations on the effect of nitro-glycerine on headaches. He adopts in the main the classification of headaches made by Dr. Day. The preparation generally used was the one per cent. alcoholic solution, though in a very obstinate case the ten per cent. solution was used, two drops being first given, and after an interval of two minutes three more (*The Lancet*). The result of this heroic medication was that the patient, a girl of fifteen, became pallid, and her pulse very weak ; however, a little water and some smelling-salts quickly revived her, and she was none the worse. The nitro-glycerine had no effect on the headache, which was of a persistent character, and was probably due to some organic lesion, perhaps an affection of the cranial bones. As a rule, two or three one-drop or two-drop doses of the one per cent. solution, placed on the tongue at intervals of a very few minutes, sufficed to arrest the headache. The conclusion arrived at was that all cases which depend entirely, or almost entirely, on a vaso-constrictor neurosis are immediately curable by nitro-glycerine. In cases where the cerebral anæmia is partly due to deficiency or poorness of blood, milk, iron, arsenic, quinine, and other tonic remedies are, of course, required in addition to the nitro-glycerine. The chief indications for the successful treatment of migraine by nitro-glycerine are pallor of the face and a paroxysmal character of the pains, also their augmentation on pressure of the carotids, and their diminution when the head is lowered. In "nervo-hyperæmic headaches" nitro-glycerine is useful, but it only acts indirectly by dilating the vessels in other parts of the system, and thus relieving the congestion in the cerebral vessels. It is positively injurious in headaches depending on passive hyperæmia. As a rule, he thinks that if nitro-glycerine fails to relieve, the prognosis is probably bad, as the pain is generally due to some organic lesion, such as thickening of the fibrous coverings following chronic alcoholism or syphilis, or to some osteophyte caused by periostitis, or, lastly, to morbid changes in the cranial bones. In some headaches of rheumatic origin nitro-glycerine appears to have some effect, but Dr. Trusevich thinks that in others massage would probably be more beneficial. Where headaches are due to heart, lung, or to hepatic disease, which causes passive congestion in the cerebral vessels, nitro-glycerine cannot be expected to do much good.

CORRECTION.—HYDRONAPHTHOL IN THE TREATMENT OF LUPUS.—Dr. Henry G. Piffard writes: "In report of my 'Note on the Treatment of Lupus,' your correspondent makes me say that of six cases treated, *all relapsed but one.* It should read *only one* relapsed."

REPORT OF CASES OF INTESTINAL OBSTRUCTION TREATED BY LAPAROTOMY.[1]

By WILLIAM T. BULL, M.D.,

SURGEON TO THE NEW YORK HOSPITAL.

It will be generally acknowledged that the treatment of intestinal obstruction is at present a very puzzling problem. Rarely do cases that present grave symptoms recover with purely medical treatment, and when they do, there is often much doubt as to the correctness of the diagnosis. When surgical treatment is adopted, the majority die. Schramm's collection of one hundred and ninety cases,[2] published in 1883, showed a mortality of 64.2 per cent. And time, which has perfected details in the operative technique and recorded an improved rate of success for laparotomy in other conditions, has not shown any bettering of the statistics of this operation for obstruction. Dr. B. Farquhar Curtis, who has just completed a collection of three hundred and fifty cases, tells me that the rate of mortality is sixty-eight per cent. This increasing rate of mortality would make it appear at first sight as if surgery were not likely to attain great success in this field. And yet I am convinced, to the contrary, that the operative treatment has not yet had the trial which it deserves, and, furthermore, that the doctrine long ago laid down by surgical writers, of early operative interference, has not yet been followed in practice by the profession at large. One has but to note the records of cases appearing frequently in the journals in order to be convinced of this. And it is interesting to note that, in recent discussions of this subject before the surgical societies of Berlin and Paris, much thought has been given to the proper procedure in cases where the cause of the obstruction is obscured by tympanitic distention of the bowels, a condition that develops gradually, and becomes of such extent as to be baffling to the surgeon only in the later stages of the disease. It may be safely averred that much of the perplexity which besets the operator in cases of late operation. much of the danger attending the patient, and a great deal of the doubt as to the proper procedure, and uncertainty as to the result, would be swept away if we would adopt the plan of early operative interference.

But it is not my purpose to discuss this point, on which I am sure most of you would agree with me, but rather to illustrate the method of operative treatment by narrating those cases which have fallen under my own observation. Of five cases three have been of an acute character. The first one, but for the distance from town, would have doubtless been operated on earlier. It is as follows:

CASE I. *Intestinal obstruction by a peritoneal band; peritonitis; laparotomy on the eleventh day; death.*—Miss F——, aged thirty, who had been previously in good health, living on a farm near Summit, N. J., and doing some household work, was seized with colicky pains in the epigastrium, July 17, 1886. After a loose passage the pain lessened. Next day it recurred, and vomiting began, which became fecal in character after a few hours, and continued. Twice or three times in each twenty-four hours one or two pints of yellow, fluid fæces were ejected. Pain was controlled by small doses of morphine. It was not severe. No cathartics were given, and no nourishment except what the stomach would hold. On the fourth day enemata of water were administered, and one or two given daily, not exceeding a quart in quantity. Twice small fecal masses were passed, but no gas. The urine was normal in quantity and appearance. The temperature had not been over 100° F.; the pulse, 100 to 120, not strong; the patient growing weaker every day. The abdomen had not been distended.

This history, unavoidably scanty in details on account of the distance of the patient from her physicians, I obtained from one of them, Dr. W. H. Lawrence, of Summit, who had urged an operation long before the friends would consent. I found the patient, on July 28th, weak from want of nourishment and much dejected; pulse, 120; temperature, 100°; respiration, 30. The abdomen was flaccid, resonant, tender only in the ileo-cæcal region; no tumor was to be felt, and rectal examination was negative. I saw the matter vomited last, and it was undoubtedly liquid fæces—at least a quart in quantity. Laparotomy was performed at once, with the assistance of Dr. B. Farquhar Curtis and Drs. Martin and Lawrence. An incision five inches long, through thin abdominal walls, disclosed the omentum spread out over and concealing the intestines, to which it was lightly adherent and attached to the parietes of the pelvis by several thin bands of recent adhesion. After ligating these the omentum and small intestine presenting, which were highly congested and slightly distended, were pushed upward with sponges so as to expose the cæcum and sigmoid flexure. Neither of these was distended. The finger, passed among the coils of small intestine toward the cæcum, detected a band passing from the right hypochondrium downward into the mass of coiled intestine. This band was drawn into the wound, and, from exploration with the finger, it seemed to be attached above to the parietal peritoneum or to the colon, where it was one inch wide and one-fourth of an inch in thickness. Its length was four inches, and it passed over and compressed one segment of small intestine, to become attached to and encircle another part of the gut about eight inches distant. This loop of eight inches of the gut was deeply congested, empty, and shrivelled; that on the other side of the band moderately distended. Near the intestine the band was the size of a lead-pencil. The accompanying cut (Fig. 1), from Poulet and Bousquet, ("Path. Externe," iii., Fig. 44) is an accurate representation of the condition. On lifting the band, the air rushed in and filled up the loop within it. The band was cut between two ligatures; the parietal, or upper end, dropped, and the intestinal end gently separated from the gut which it encircled. The circumference of the gut before this separation was about that of the index-finger, but its walls appeared healthy. On lifting up the disengaged loop, however, a few drops of fecal matter escaped through a small softened or gangrenous spot one-eighth of an inch in diameter. This was cut out, making a wound an inch long, and parallel to long axis of the gut, which was closed with twelve Lembert sutures. The cavity was carefully washed out with 1 to 10,000 bichloride solution. The operation lasted one hour and forty minutes, and the patient was profoundly depressed by it. The pulse increased to 140 after the cavity was opened, and never diminished in frequency. There was no more vomiting, and no pain. Consciousness was regained in about two hours, and maintained till half an hour before death. The temperature was 97¾° for several hours after operation. Later it rose to 105°, and fell a little. Death occurred about twenty hours after the operation.

Here was a mechanical condition easily discoverable, and remediable by a short operation, allowed to remain undisturbed for eleven days, while the patient was suffering from inanition and the intestine was being slowly strangled by a band. There was no obscurity of diagnosis; but help came too late. Peritonitis was beginning, as shown by the adhesion of the omentum to intestines and parietes. The manœuvre of wedging back with several sponges the gut presenting in the median line is worthy of note, as it allows the inspection of both sigmoid and cæcal regions, unless the tympanites be very great. The easy detection of a band by the finger among the coils of gut is also of interest. The gentlest manipulation of this band and the intestine it embraced did not prevent a softened spot from giving way and allowing the escape of fæces—an event which would not have happened had the operation been possible three or four days earlier.

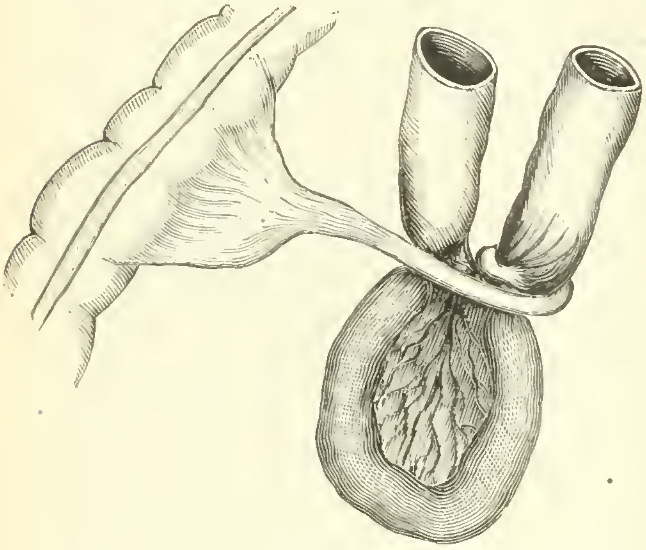

Fig. 1.

Case II. *Acute intestinal obstruction caused by peritoneal band; laparotomy on the sixth day; recovery.*—Mrs. V——, aged twenty-six, married, but without children, had suffered from perimetritis, or some pelvic inflammation, two years before present illness. On November 5, 1887, after a hearty lunch, she was seized with severe cramps in the abdomen, and vomited the contents of the stomach shortly afterward. The pain and vomiting continued, without fever, and a pulse of 100, and on the third day the abdomen was slightly swollen. Pain was referred to the lower part. Enemata were given every day for five days, twice, copious in quantity (two quarts), and in the knee elbow position, but only small particles of fæces and no gas were evacuated. Treatment was morphine, liquid diet, and rectal enemata. On November 10th, the fifth day of the attack, I saw the patient, with Dr. George T. Harrison. The pulse was 100; temperature, 99°. Tongue was moist, slightly furred. She complained of great thirst and general abdominal pain, and vomited a brownish mucus. Urination was normal. The abdomen was slightly swollen, nowhere tender, and presented no tumor. Nothing in rectum. Treatment continued, with the addition of irrigation of the stomach. Twenty-four hours later, November 11th, the sixth day of the attack, the condition was unchanged, and laparotomy was performed, with the assistance of Dr. Harrison, Dr. G. B. Phelps, Jr., and Dr. Claiborne. On opening the abdomen by an incision four inches long, a small quantity of odorless, bloody serum escaped, and moderately distended coils of small intestine presented themselves, deeply congested, but free from exudation. The finger, passed into the cæcal and sigmoid-flexure region, discovered no band, tumor, or stricture, but a loop of empty gut was felt and brought to the surface after enlarging the wound to a length of six inches and pushing the distended intestine aside with sponges. The empty gut was the cæcum and about two inches of the ileum. By gentle traction I followed this empty gut into the depth of the cavity, where, to the finger, it seemed to pass behind the mesentery or under a false ligament.

It was impossible to see this point, but in manipulating the sponges and retractors, in order to bring it nearer, there came into view the appendix, with a slender band of tissue stretching from its extremity to a loop of small intestine. This band was of the size of a knitting-needle, an inch in length, and was red and raw, as if torn from a large mass. It was cut between two catgut ligatures. The intestine exposed to view was then drawn out farther, till three inches of cæcum and ascending colon, and about four inches of ileum could be seen. At a point four inches from the ileo cæcal valve there was a circular groove about its circumference, where the peritoneum had lost its glistening character and was opaque. This was about one-sixteenth of an inch wide. Above it the gut was deeply congested and distended, half as large as the wrist; below it the gut was of the size of the thumb and not congested, but along its mesenteric border were one or two places which appeared to have been the seat of ruptured adhesions. There was no thickening of the coats of the intestine, and during the investigation the empty part became a little congested and the contents passed freely by the circular mark described and into the cæcum. Dr. Harrison and I concluded that this band encountered at first had constricted the small intestine at the situation of the circular marking, and that the manipulation of the gut had ruptured some adhesions and released the gut *before* the band was divided. We did not think it prudent to remove the distended intestine from the abdomen, nor to open it, and, after washing out the cavity with warm 1 to 10,000 bichloride solution, closed the wound.

After operation patient vomited but once. The pulse was never above 90 or 100. The temperature was 99° or 100° at night for the first forty-eight hours. Liquid nourishment was retained, and a copious fecal evacuation occurred after a bottle of citrate of magnesia and an oxgall enema on the morning of the third day after operation. The general condition rapidly improved, but complete recovery was delayed by an abscess in the abdominal wall. While recovery ensued without an untoward symptom in this case, the patient would have had better chances from an earlier operation, and the symptoms were certainly sufficiently pronounced to warrant it. The chief reason for delay was that the mother of the patient, her only living parent, was at a distance from the city. She was telegraphed for, but, when no improvement was noted in the first twenty-four hours that I observed her, the operation was done without waiting for her arrival. The band in this case was evidently soft and easily torn, and, had not the grooving of the intestine been seen, the success of the operation would have been unexplained. The easy recognition of the empty intestine suggests a search for such a condition as an important step in the technique.

Case III. *Acute obstruction in cancer of the sigmoid flexure; laparotomy and artificial anus on the seventh day; recovery.*—Mrs. S——, aged fifty, was visited, with Dr. F. M. Townsend, March 11, 1886. She had had no serious illness except a series of attacks of intestinal obstruction during the three years previous to the present one. The first was in March, 1884; in 1885 there were two, and one in January of this year. These were characterized by violent colicky pains, with constipation and moderate vomiting, without swelling of the abdomen. The symptoms yielded after the administration of cathartics—the pulv. jalap co. having been given several times by Dr. Townsend in doses of forty grains. The duration of the attacks varied from four to ten days. In the intervals she was well, and relied on the regular use of Hunyadi Janos water to secure daily movements. The passages were never misshapen, nor did they contain blood or mucus. A fibroid tumor of the uterus had existed for two years, and was large enough to nearly fill the pelvis, but occasioned no symptoms. March 5, 1886, the present attack began, like the others, with pain, nausea, and constipation. On the second day there was vomiting, which continued. Calomel, pulv. jalap co., and ol. tiglii, and several copious injections of water were of no avail. On the sixth day, when I saw her, the vomited matters were fecal in odor, and the abdomen was moderately distended. The pulse was rapid; the temperature 100°. The features were slightly pinched, the surface warm, the tongue dry. The abdomen was not tender; no tumor could be felt. Urine normal, but small in quantity. Rectal examination by sound and by finger was negative, except that the presence of the fibroid tumor was made out. An operation was advised, but twenty-four hours elapsed before consent was given. March 12th, the abdomen was opened in the median line by an incision four inches downward from the navel. I exposed the surface of the uterine tumor by pushing back the moderately distended small intestine with sponges. It occupied the greater part of the pelvis, but there was no intestine compressed by it. Cæcum felt natural, but between the centre of the sigmoid flexure and the beginning of the rectum there was a hard annular stricture, half an inch in width, which made a deep circular furrow in the gut. No mesenteric glands could be felt, but the mesentery was fully an inch thick from fatty deposit. The gut above the stricture was but slightly dilated and congested. Although the stricture was undoubtedly cancerous, I could not reasonably entertain the idea of resection. The situation was too low down for suitable manipulation, and the patient too weak for a prolonged operation. A portion of gut, distant only an inch from the stricture, reached to the centre of the incision without tension. It was accordingly fixed in the middle third of the median incision by suturing it with catgut to the peritoneum, after that membrane had been sutured to the skin. The gut was not opened. The general condition of the patient was not desperate; some gas had passed through the stricture during the manipulations, and I thought it wise to allow some hours for adhesions to form. The duration of the operation was one hour, and the general condition was not notably affected by it. Morphine was continued, with nutrient enemata, and a cold-water coil applied. Vomiting occurred only once, the temperature was not over 101°, and the pulse rapidly improved. Ten hours after the operation I punctured the gut and allowed more gas to escape, and twelve hours later several pints of fluid and pasty fæces escaped through the puncture. Following this, food by stomach was given, and recovery was rapid. The wound above and below the artificial anus united primarily; the edges of the anus retracted so as to leave an opening the size of the index-finger, into which the mucous membrane projected. After the patient got out of bed, she ate liberally and took exercise; the movements took place regularly every morning. She gained flesh, and three months after operation was in every way better than for two years past, although she complained much of the annoyance of the artificial opening. A small quantity of fæces passed the stricture, and required an enema every ten days or two weeks for its dislodgement. Six months after operation I saw her again, and found the anus narrowed by a hard tumor of the size of a walnut, which occupied the lower half of its circumference, and projected above the level of the skin and was ulcerating on its surface. The orifice of the anus admitted the tip of the little finger with difficulty, and a second rounded, hard mass could be felt just within its upper edge. The passages were sometimes of the size of a lead-pencil, though the anus had been dilated daily with urethral bougies for several weeks by Dr. Townsend, and cathartics were necessary almost daily in order to get a movement without great efforts. But the general health was excellent. Excision of the growth was recommended, but not consented to till four months later, in January, 1886, ten months from the first operation. In the interval, notwithstanding the increasing difficulty of defecation, owing to the growth of the tumor into the lumen of the anus, its cauterization by arsenic paste, the constant discharge of mucus, and several hemorrhages, the general health and strength was apparently unimpaired. The excision of about four inches of intestine, including the artificial anus and the cancerous stricture, was done twelve months ago, and she has been ever since in better condition than before. There is no sign of recurrence at the present moment, and the patient is eager to have the new artificial anus closed by operation, which I propose to undertake within a month or two, if her good condition continues.

The timely interference in this case rescued the patient from a dangerous situation, and placed her in the best condition for subsequent operation for the removal of the neoplasm. Although that secondary operation was so long deferred, the result seems likely to be satisfactory. Up to the present time nearly two years have been added to her life, and her existence, despite the unnatural anus, has been a contented one. In all cases of malignant stricture requiring operation for obstruction, I believe it preferable to pursue the plan which I adopted in this and the following case, of relieving the obstruction first, by the formation of an artificial anus, and leaving to a later operation the removal of the neoplasm by resection.

CASE IV. *Chronic intestinal obstruction from cancer of sigmoid flexure; laparotomy and artificial anus; recovery.*—August 14, 1886: Mrs. J——, aged sixty, has had no severe illness, and childbirths have been natural. She is well preserved, and of hearty appearance. She has always been of constipated habit, and for several years past has taken laxatives to bring about movements, but has never had any attack of acute obstruction.

Six weeks ago, when constipated, was seized with severe pains in abdomen, with nausea but no vomiting, and since that time had had no movement from the bowels. After copious injections, a few teaspoonfuls of well-formed fecal matter have been passed, but nothing more. Purgatives have caused vomiting. Wind has passed freely. There have been frequent paroxysms of pain, unless suppositories of morphia (gr. j.) and belladonna (gr. ss.) were employed. Two days ago, under ether, an O'Beirne's tube was introduced thirteen inches, and two quarts of water introduced through it. This was followed by a trifling amount of fæces. Her diet has been of fluid character, and rectal injections have been freely used. Her general strength has kept up well; much of the time she has been out of bed, and she has withstood a journey from Asbury Park to-day without marked fatigue.

Pulse, 96; respiration, 18; temperature, 98½.° Tongue clear and moist. The abdomen is slightly distended, but flaccid, and nowhere tender. In the lower iliac and lower lumbar region an indistinct mass of the size of a banana is felt. It is not fixed to the wall of abdomen or pelvis, and percussion over it is normal. After palpation of the abdomen for several minutes, by Dr. A. B. Ball and myself, the peristaltic movement of the intestine could be detected in the umbilical region and on the right side, and the mass felt on the left side changed its shape—and even at one time disappeared. Liver, spleen, and heart normal. Rectal examination negative. Urine is said to be normal in quantity.

Two days later Mrs. J—— was visited by Dr. Janeway, who passed the rectal tube again for me. Three pints of warm water were injected, held a few minutes, and then passed, with the addition of a tablespoonful of flaky fecal matter. It was thought by both Dr. Janeway and Dr. Ball, as well as myself, that the most probable diagnosis was cancerous stricture of the sigmoid flexure, though the possibility of impaction of fæces was admitted, as well as constriction ot the gut from some other cause, such as adhesions and bands. Explorative laparotomy was recommended. Dr. Didama, of Syracuse, had previously expressed a similar opinion. At the urgent request of the family, attempts to effect a movement by injections were continued.

August 23d.—The general condition is about the same. No fever; pulse ranges from 80 to 100. There has been more pain in last two or three days, requiring three or four suppositories per day to overcome it. The diet has been fluid in character, with two or three enemata of "liquid peptonoids" daily. Vomiting only once. Wind has been passed freely, but no sort of injection has produced a movement. A long tube has been twice passed, and two pints of warm water injected; a shorter flexible tube (eight inches) has been introduced every day. Olive-oil, glycerine and water, and soap-suds have been injected in various quantities and held for some hours, but in vain. The greatest amount of fecal matter has been passed in the intervals of the enemata—voluntarily, or after the peptonoids had been introduced. This has never been more in quantity than half a tablespoonful. It seems evident that the fluids pass through the seat of obstruction, and that small amounts of fæces get through at intervals and accumulate in the rectum. Urine is acid, contains no albumen; specific gravity equals 1.014.

August 24th.—Laparotomy was performed, with the advice and assistance of Dr. Douglas Morton, of Louisville, Ky., Dr. B. Farquhar Curtis, and Dr. H. C. Coe. After opening the abdominal cavity by a median incision four inches in length, the hand encountered at once the distended sigmoid flexure, which reached well over to the median line and was as large as one's wrist. Its walls were more rigid and more parchment-like than normal, its serous coat congested, and it was partly concealed by coils of small intestine of normal appearance. On tracing the flexure toward the pelvic cavity a narrow annular constriction was met with close to the beginning of the rectum. The diameter of the gut here was not greater than one inch, the width of the ring of constriction being about one-fourth of an inch. In the mesocolon adjoining was an area of infiltration, one-half by three inches. This could not be seen, although the stricture was brought into view by wedging the small intestine out of the way with sponges. There was a small quantity of clear serum in the pelvic cavity. Twenty minutes were spent in getting this information, from the time the administration of ether was begun.

It was not possible to resect the strictured part of the gut with its mesocolon, for it could not be brought up to the level of the abdominal wound. I should not, however, have ventured on so hazardous and unpromising an operation in so old a subject. The choice of procedures lay between an artificial anus in the median line, and a left lumbar colotomy. The former seemed to me the wiser, as it offered a relief to the obstruction at once, without complicating or prolonging the operation materially. The lower three-fourths of the incision were closed by silk sutures (through all the layers). In its upper fourth the peritoneum was sewed to the skin with a continuous catgut suture, and the wall of the distended gut, at a point about four inches above the stricture, sewed to the peritoneum in the same way. The gut was not opened. The duration of the operation was forty-five minutes, and the patient was placed in bed in good general condition. At the end of twenty-four hours the temperature was 100°; pulse, 120; and there were pain and vomiting. These symptoms ceased after incision of the wall of the colon, thirty hours after operation. A copious evacuation of soft fæces occurred, nourishment was retained, and recovery was rapid. At the end of four weeks Mrs. J—— travelled to Louisville, without discomfort. She is reported to me as being in pretty good health, able to make a journey to Florida, though there are signs of the growth in the vicinity of the artificial anus. She and her family have been opposed to a secondary operation.

The experience of these two last cases has demonstrated to me that the location of the artificial anus in the median line is more convenient for the patient than in either lumbar or inguinal region. And it has the further advantage of being a simpler procedure, and one requiring less time and involving less hemorrhage than the making of an opening in the other localities.

CASE V. *Obstruction from cancer of rectum; laparotomy; death.*—Mr. L——, a lawyer, aged thirty-seven, was first seen by Dr. C. H. Knight in the latter part of November, 1887. He had for several years had occasional attacks of diarrhœa, with pain, and in the last year there has often been severe pain at stool. The passages have been always loose, without blood or mucus, and in the past six months he has lost much flesh. The examination of the abdomen and rectum was negative. Two weeks before I saw him he had severe abdominal pain, with vomiting, tympanites, and sharp peristalsis. Enemata brought away a small amount of fecal matter during the first three or four days, the vomiting ceased, the pain moderated. Pulse was 100; temperature, 100°; and there was no abdominal tenderness. But the distention increased, no flatus was passed, and enemata failed to produce any fæces. A small rubber bougie would pass only five inches into the rectum, and it was observed that the quantity of water which the patient could retain rarely exceeded six or eight ounces. Urination normal, but quantity diminished.

December 24, 1887, in consultation with Dr. G. L. Peabody and Dr. Knight, laparotomy was advised, and the operation performed immediately with their help and that of Dr. G. B. Phelps. The tympanitic distention of the abdomen was extreme, but in other respects the condition was good. On pushing the finger vigorously into the rectum its tip seemed to encounter a hard mass, but the sensation was very indefinite. Still, we felt sure that the exploration would discover a stricture of the sigmoid flexure or rectum from the history of the case. At 10 P.M., after opening the abdomen under ether, it was with much difficulty that the swollen small intestine could be displaced sufficiently to permit digital exploration of the pelvis. Seeing was impossible. But in the upper part of the rectum a hard, flattened mass was detected, which could be caught between one finger inside and another pushed far up the rectum. The sigmoid flexure would not reach to the median line, and consequently it was affixed to the abdominal wall (peritoneum to peritoneum), on the left side of the rectus muscle, by an incision parallel to Poupart's ligament and two inches above it. The bowel was not opened, but the wall had been torn at one point by the teeth of a forceps, which permitted the escape of some gas. More escaped during the night, but there was no visible lessening of the distention. Fæces were passed freely during the day of December 25th, but the pulse became very rapid, the surface cool, the temperature did not rise, and death followed eighteen hours after the operation.

At the autopsy Dr. Peabody found evidences of commencing peritonitis, but no fecal matter in the cavity, though the gut was not closely adherent to the parietal peritoneum. The omentum was turned up on the stomach, and contained carcinomatous nodules, and the mesenteric glands were likewise affected. Six and a half inches from the anus there was a cancerous deposit in the wall of the rectum, causing it to adhere to the posterior surface of the bladder. This was annular in form, one inch long, three quarters of an inch thick, and the lumen of the bowel was diminished to the size of a lead pencil.

In this instance, examination with the finger in the rectum gave vague indications of the presence of a stricture. The introduction of the whole hand would have made the situation clear, and inguinal or lumbar colotomy would have been the proper procedure. I omitted this examination, because there was not present anyone with a hand the dimensions of which would have made the exploration safe. With the fingers extended and folded together, a safe hand should not exceed eight inches in circumference. The evidence furnished by exploration with a bougie and by the quantity of water retained is justly regarded in general as fallacious; but in this case it was undoubtedly correct.

It will be seen, from the histories of these cases, that I have operated as early as consent could be gained, and with a good measure of success. But in all of them still earlier interference would have been better surgery and more advantageous to the patient. It is difficult to adhere to a rule that an operation should be done at a given time from the onset of an attack. Either the danger is not appreciated by the physician in attendance, or the friends object, or some variation in the symptoms leads to the hope that medical measures may suffice. Much valuable time is lost in efforts at refinement in diagnosis, such as the location of the seat of obstruction and the determination of its nature. I do not mean to speak lightly of the information we possess, which will sometimes enable us to arrive at valuable conclusions in these respects, but I think the deciding of the main question, Does intestinal obstruction exist? is more important. This conclusion once reached, medical measures may be resorted to. If they fail to relieve at the end of from twenty-four to forty-eight hours, the operation should be performed. In this I refer, as a matter of course, to acute obstructions. In chronic cases, like the last two narrated, it is proper to delay longer. The persistence of pain which requires morphine for its relief, the continuance of vomiting, the failure to provoke a movement by several rectal enemata, aided by mild aperients, these symptoms, with or without commencing tympanites and without fever, should invite the attention of the surgeon, and demand operative interference unless promptly relieved. The operation decided upon, an incision large enough to admit the hand should be made, and the presenting intestine pushed away to permit inspection of the rectum, cæcum, and sigmoid flexure. Then bands may be felt for, or empty loops of intestine, and this failing to discover the lesion, the gut may be searched, while still inside the belly, for congested or distended portions. This can be done rapidly, if the edges of the abdominal wound be strongly retracted. Removal of the small intestine from the cavity, or "eventration," which has been advocated by Kümmell, seems to me a very serious step. In has, in the instances where I have done it for gunshot wound, invariably produced great shock. It might seem proper if the intestine were *not* heavy from congestion and enlarged by distention; but when such a condition exists, I think enterotomy would be preferable to "eventration," or to the emptying of the gut by incision, as proposed by Greig Smith.

I would like to add to these cases notes of five others which I have seen with Dr. F. P. Kinnicutt, Dr. J. B. Hunter, Dr. J. D. Anway, Dr. W. H. Farrington, and Dr. G. T. Harrison, but it is impossible, since I saw the patients but once. But in all of them the symptoms, pronounced at the outset, disappeared within seventy-two hours under medical treatment. In all, then, I have met with ten cases of intestinal obstruction, five of which have recovered within three days. The other five have been operated on, with two deaths.

Epitaph on the Grave of a Dentist:

"View this gravestone with all gravity,
I . . . is filling his last cavity."

REPORT OF A CASE OF TUBAL PREGNANCY ADVANCING TO FULL TERM WITHOUT RUPTURE.

By CHARLES E. TAFT, M.D.,

LATE HOUSE SURGEON TO THE WOMAN'S HOSPITAL IN THE STATE OF NEW YORK.

The patient, aged thirty four, was admitted to the Woman's Hospital in the State of New York, into the service of Dr. T. Gaillard Thomas, January 17, 1888. Her health had always been excellent, and she had passed through two perfectly normal pregnancies, the last having occurred ten years previous to her present trouble.

About a year and a half ago she began to notice again the usual signs of pregnancy, having amenorrhœa lasting seven or eight months, with gradual enlargement of the abdomen, swelling of the breasts, and for a period of two or three weeks well-marked morning sickness. Between three and four months after she became pregnant she commenced to "feel life," and this she noticed from time to time for five or six months. Nine months after she first missed her menstruation, milk appeared in her breasts, and then she was very firmly convinced that she was enceinte.

In February she had a profuse flowing lasting one week, and during this time large clotted masses came away. For quite a while after, this was supposed to have been a miscarriage. Since that time, at intervals of a few weeks, but irregularly, she has had moderate flowing, passing also a few clots. Previous to this pregnancy her menstruation was always normal and regular.

From February, 1887, to the following July, her abdomen gradually diminished in size, and since has varied but little. Although she had lost some flesh, as was her custom during a pregnancy, she was still in fair health and but little emaciated up to three months ago. She then commenced to run down, losing flesh and strength, and soon became unable to do her housework. At intervals since, she has had slight fever toward night, with occasional night-sweats, and several times in the past two months has had chills.

During the past year she has consulted physicians frequently, and five weeks ago she was examined under chloroform by several doctors in Jersey City. The treatment adopted was palliative or tonic, and the real state of affairs does not seem to have been surmised.

At the time of admission she complained of anorexia, weakness, and more or less sharp pain in the side and lower abdomen, aggravated by walking or any exertion. The evening temperature averaged 99° to 100° F.

Palpation of the abdomen revealed in the median line an evenly rounded, rather tense, elastic, and freely movable tumor, extending upward as far as the umbilicus, and about the size of a pregnant uterus at six months. To the left and in front, just behind the pubes, and apparently attached to the mass, was a hard body which was evidently the slightly enlarged uterus. Vaginal examination confirmed what external palpation seemed to indicate. On bimanual palpation the uterus seemed to move with the tumor, although it was very difficult to determine this point, and indistinct fluctuation was thought to be present. Ballottement was negative.

Laparotomy was very strongly advised by Dr. Thomas, and was consented to by the patient.

After the usual preparatory treatment customary at this hospital, which consists of moderate catharsis for several days, warm baths and tonics, followed by an enema of soap suds, the patient was anæsthetized at 3 P.M., January 21st.

The operation was performed by Dr. Thomas, Drs. Chambers, Nicoll, Taft, Aspell, and Baldwin assisting. An incision about four inches long. afterward lengthened to six, was made in the median line, between the umbilicus and pubes. But little bleeding ensued. On snipping the peritoneum, a tumor with very vascular coats and of a light purple color presented. A sound swept over its surface revealed no adhesions. The tumor seemed to contain fluid. The patient was then turned on her right side, and a small trocar and cannula inserted into the sac, when, on removing the trocar, a thick, purulent-looking fluid escaped. The operator then incised the tumor, seized the edges of the sac with cyst-forceps and large hooks, and, enlarging the opening, introduced his hand and extracted a full-grown child, somewhat macerated. The lower surface of the sac was quite adherent, and it was not thought advisable to attempt its removal, and, on account of the danger from hemorrhage, it was determined to leave the placenta *in situ*.

Further examination of the sac showed it to be covered everywhere with peritoneum, its wall to be $\frac{1}{4}$ to $\frac{1}{2}$ inch thick, to contain muscular coatings, and to be intimately connected with the right horn of the uterus. The sac, in other words, seemed to be unquestionably an enormously distended Fallopian tube. The body of the uterus was apparently perfectly developed, there being no evidence of any bifurcation. The patient was so very weak that Dr. Thomas determined to sew the edges of the sac into the abdominal wall, and allow the placenta to slough away, instead of removing the sac. On trimming off the edges of the sac there was considerable hemorrhage from the very vascular walls, but this was readily checked by a continuous catgut suture uniting them to the peritoneum and abdominal walls. A few interrupted sutures of silk were afterward added to strengthen the line of union. The sac was next thoroughly washed out with a solution of corrosive sublimate, 1 to 5,000, and strong carbolic acid applied to the edges of the wound. A dressing of iodoform gauze was packed into the sac about the placenta, and covered with a thick layer of absorbent cotton and bandage.

On coming out of ether the patient's pulse became quite weak, and her breathing very shallow, but by vigorous stimulation and elevation of the extremities, after a period of two or three hours she rallied. Very little nausea followed the operation. On examining the wound at this time for hemorrhage, it was noticed and remarked by all that the sac had contracted more than one-half. For the first twenty-four hours continuous antiseptic irrigation of the sac was kept up, and after this, until the removal of the placenta on the ninth day, washing out of the sac was performed every two hours. Until the eighth day the temperature did not rise much above 100° F., and the pulse averaged 80 to 100 per minute. By this time considerable sloughing was going on in the sac, and Dr. Thomas removed, with the placental forceps, the greater portion of the after-birth, which was quite friable. No hemorrhage took place. Since then the patient has done uninterruptedly well, and has now entirely recovered.

Examination of the fœtus showed it to be a male child, about seventeen inches long. It undoubtedly had been macerating in the purulent contents of the sac for some time.

During the operation the patient, on two occasions, became so much exhausted that a fatal issue seemed imminent. Dr. Thomas has since declared his conviction that, had he removed the sac, the patient would surely have died.

Cases of tubal gestation advancing to nearly, or quite, full term are very rare. Several cases are historical, and are quoted in most of the recent works on obstetrics. In rather a hasty research in the limited time at my disposal, I have been able to find eleven cases that have reached eight months without rupture of the tube.

In this search I have been very much assisted by Dr. R. P. Harris, of Philadelphia, who kindly furnished me with references to several cases.

Spiegelberg[1] reports a case of his own, and also one by Saxterp, and another by Fabbri, all going to full term. Hofmeier[2] reports a fourth case. Simpson[3] and Tinker had one each at full term. Dillingworth had a case reaching eight months. Orten,[1] of Broome County, N. Y., reports a case in which the fœtus advanced to full term, and remained *in situ* fourteen years, and where his diagnosis was confirmed by a post-mortem held by himself and Dr. C. P. Tucker, of New York. In the discussion which followed the reading of the paper describing this case, before the New York State Medical Association, Dr. I. E. Taylor, of New York County, referred to a case which occurred in Bellevue Hospital, the patient being eight and a quarter months pregnant, and dying of a hemorrhage following rupture of the Fallopian tube, in which the fœtus was contained. He stated that the specimen was placed in Wood's Museum.

Zitzman[2] and Brendel[3] each report a case where they removed by gastrotomy a dead fœtus, at nearly full term, from a sac which was probably the greatly distended Fallopian tube.

The convalescence of the case which I report was remarkable in several respects. The patient certainly looked and felt as well as any woman following the first week of a normal labor. Indeed, I may say that she has done better in every way than any case of ovariotomy which I have yet seen, where the sac was adherent and stitched into the abdominal wound. Her appetite has been excellent. There has been an entire absence of odor, and this, in the presence of a sloughing placenta, I attribute to the large, free opening in the sac, permitting thorough and frequent irrigation, with early removal of the sloughing fragments.

While I was able to find quite a large number of cases in which the fœtus reached a development of four months before rupture of the tube, I could find but very few, indeed, where the death of the fœtus and rupture of the sac took place between four and eight months; and from the rarity of the latter cases, it seems not improbable that, having passed four or five months, there is a more than even chance of the pregnancy reaching the period of viability before rupture of the tube or death of the fœtus occurred.

This is the fifth case of extra-uterine pregnancy advanced beyond full term which has been treated by laparotomy by Dr. Thomas. Four of these occurred in this hospital. All five cases recovered; a remarkable record, when the extreme rarity and gravity of such cases are considered.

MAURICEAU ON MULTIPLE BIRTHS.—Francis Mauriceau, in his treatise on "The Diseases of Women with Child," Paris, 1668 (*Medical Classics*), discourses as follows regarding multiple births: "There are daily women brought to bed of two children at once, sometimes of three, and very rarely four. Yet I knew one Mr. Herbert, converer of the king's buildings, who was so good a coverer that his wife, about seventeen years since, brought forth four living children at a birth; which the Duke of Orleans, deceased, coming to hear of, to whom (because of his jovial humor) he was very welcome; the Duke asked him (in the presence of divers persons of quality) whether it were true that he was so good a fellow as to get his wife with child of those four at one bout? He answered very coldly, Yes, and that he had certainly begat at the same time half a dozen, if his foot had not slipt; which made them all laugh very heartily. But I esteem it either a miracle or a fable, what is related in the history of the Lady Margaret, Countess of Holland, who, in the year 1313, was brought to bed of three hundred and sixty-five children at one and the same time; which happened to her (as they say) by a poor woman's imprecation, who, asking an alms, related to her the great misery she was in by reason of those children she had with her; to which the lady answered, She might be content with the inconvenience, since she had the pleasure of getting them."

NOTES OF TWO CASES OF REFLEX PARALYSIS OF ACCOMMODATION OF THE EYE, WITH MYDRIASIS, DUE TO DENTAL IRRITATION; WITH OBSERVATIONS UPON THEIR SUPPOSED BEARING ON THE QUESTION OF THE PATHOGENESIS OF SYMPATHETIC OPHTHALMITIS.[1]

By SAMUEL THEOBALD, M.D.,

ONE OF THE SURGEONS TO THE BALTIMORE EYE, EAR, AND THROAT CHARITY HOSPITAL.

Case I.—Mr. J——, a merchant, aged twenty-six, who had never had syphilis, and who had had no previous trouble with his sight, consulted me on July 1, 1873, on account of a disturbance in the vision of his left eye, of twenty-four hours' duration. The pupil of the affected eye was found to be dilated, and upon testing his near vision, almost complete paralysis of the accommodation of this eye was discovered. Its distant vision was $\frac{20}{xxx}$, but its near vision so poor that J. No. 10 could be read with difficulty at 12″. In searching for a cause for this sudden impairment of vision, I learned that for some time he had been annoyed by the existence of a suppurative inflammation about the root of the left, upper, lateral incisor tooth, the nerve of which had been previously destroyed by a dentist. The tooth was decayed, but was not painful, although there was a constant discharge of pus from its socket. However, for several days before the appearance of the eye trouble, and after exposure to wet and cold, pain of an unusual character to the patient, who was not subject to neuralgia or rheumatism, was felt in the face and head.

It seemed to me highly probable that the tooth was the cause of the ocular paralysis, and I therefore advised that it should be extracted, which was done three days subsequently, on July 4th. I also prescribed ten grains of iodide of potassium, to be taken three times a day, and a blister to be applied to the forehead. No change for the better had taken place when the patient was next seen (July 8th). I then directed an ointment, containing equal parts of extract of calabar-bean and lard, to be rubbed upon the forehead and brow at night; and on the 13th ordered, in addition to the iodide, $\frac{1}{24}$ grain of sulphate of strychnine, to be taken three times a day. On the 18th I began the daily application of the faradic current. The use of the calabar-bean produced temporary contraction of the pupil and increase in the accommodative power, but no appreciable improvement had manifested itself up to the 29th, at which date I decreased the dose of iodide of potassium to five grains, and gave in addition $\frac{1}{48}$ grain of biniodide of mercury. Within a few days after this the condition of the eye began to improve, and by August 4th he was able to read with it J. No. 6, and the size of the pupil had lessened very perceptibly.

As I left home for several weeks on the following day, I did not see the patient again until the end of the month (August 31st), when I met him upon the street. The left pupil was then of the same size as the other, and he reported that the sight was again all right, and that it had been so for about ten days. He had continued to take the remedies for a while after his last visit to me, but soon stopped all treatment, as his eye gave him no further annoyance. In response to a note of inquiry, he writes me (January 14, 1888) that the eye has never given him any further trouble, and that the sight is "perfectly good."

Case II.—Mr. M——, thirty-five years of age, a man of independent means and without occupation, was first seen by me on October 19, 1885. He stated that he had been conscious of something being wrong with his right eye for about two weeks. There had been no decided pain in it, but it felt uncomfortable and as though it were swollen. He denied ever having had syphilis, and stated that he had not suffered with rheumatism. He was, however, of a decidedly nervous temperament. Upon testing the vision of the affected eye, the pupil of which was only slightly enlarged, complete paralysis of accommodation was discovered; the lids were also perceptibly retracted, so that the palpebral aperture appeared larger than that of the other eye—the effect being just such as we are now familiar with from the instillation of cocaine. Upon testing the responsiveness of the pupils, to my surprise, I found that they were *both* absolutely motionless—neither in response to varying degrees of light, nor during changes in accommodative tension, did either undergo any perceptible alteration in size. The patient also mentioned that he had noticed that his taste, especially for sweet things, was impaired. The distant vision of each eye was nearly normal, $\frac{20}{xx}$ (?), and with the left eye he could read J. No. 1. With the right, however, he could with difficulty make out J. No. 11, and could do this only by holding the page off to about 18″. The ophthalmoscope showed the fundus of each eye to be healthy and the media clear. Upon further investigation I discovered that the crown of his right, upper, lateral incisor tooth had been broken off, and that about the root, which remained, and which was probably dead, there was considerable inflammation, the alveolar process over it being swollen and sensitive to pressure. The appearance of the gum suggested the existence of a fistulous opening from the alveolus, although he was not aware that there had been any discharge from the tooth.

He was advised to have the offending tooth, or at least what was left of it, extracted without delay. This he did at once, and on the following day there was not only a diminution in the swelling and tenderness of the gum, but a perceptible improvement in the accommodation of the eye, J. No. 9 being read tolerably well, and even some words of J. No. 8. This change, it will be observed, took place before any treatment, except the removal of the tooth, had been employed. At his second visit (October 20th) I prescribed for him biniodide of mercury (gr. $\frac{1}{32}$) and iodide of potassium (gr. j.), three times a day. Subsequently the dose of biniodide was increased to gr. $\frac{1}{24}$ and then to gr. $\frac{1}{16}$, and that of the iodide of potassium to gr. v. Strychnia was also given in doses of gr. $\frac{1}{24}$, three times a day, and an ointment of mercury and extract of opium was ordered to be applied to the forehead and temples at night. A few applications of eserine were also made to the eye, and their immediate effect upon the pupil and the accommodation was very decided, but they were soon discontinued, as they evidently had no curative action. On the 27th he reported an improvement in his taste (especially for sugar), but as yet there was no appreciable change in the pupil or further improvement in the sight. On November 23d the mercury was discontinued, as his bowels were disturbed by it, and the iodide of potassium given by itself; a blister was also applied to the right temple. On the 25th the right pupil, for the first time, responded perceptibly to light, but not until December 1st did the accommodation begin to show decided improvement. In the meantime the strychnia, which he had been taking for several weeks, had been discontinued, and syrup of phosphate of iron, quinine, and strychnia substituted. On December 12th the iodide of potassium was omitted. On December 30th the right eye was able to make out some words of J. No. 1. On January 5, 1886, I observed that the right pupil was smaller and rather more responsive to light than the left, and upon testing the far and near point of each eye with a $+\frac{1}{10}$s. lens, I found that there was but little difference between the two eyes, and that the range of accommodation in each was below what it should be. The result obtained was: L. E., $\frac{1}{A}=\frac{1}{8.1}$; R. E., $\frac{1}{A}=\frac{1}{9.1}$. All treatment was now discontinued. A week later the right eye could read J. No. 1 with ease at 9″, and this was also the near point for the left, and the pupils were of the same size and equally responsive to light. Some time before this the retraction of the lids of the right eye and the impairment of taste, to which reference has been made, had disappeared. On February 2d I tested the eyes for astigmatism, finding in each Ah. $\frac{1}{36}$, for which I prescribed plano-cylinders. At this visit the left pupil was observed to be larger and less reponsive to light than the right. On February 5th this difference in the size of the pupils was more decidedly marked, and the left one showed no perceptible response to light. The range of accommodation of each eye was again tested, and now the right eye was found to have the advantage, the result being: L. E., $\frac{1}{A} = \frac{1}{9 \cdot 1}$; R. E., $\frac{1}{A} = \frac{1}{6 \cdot 7}$. He was now complaining of tenderness and discomfort about the left, lower, anterior bicuspid tooth, the nerve of which had been destroyed, and which his dentist had recently filled, after treating an abscess at its root; and as the mydriasis and failure of accommodation in the left eye were becoming more and more pronounced, he was advised to have this tooth removed. This he consented to do, and on February 11th it was drawn. The accommodative power of the left eye, however, continued to decline, and by March 1st he could with difficulty read J. No. 3 with this eye, even with the aid of his astigmatic glass ($+\frac{1}{36}$ c., ax. 80°). With the originally affected eye, the right, he could read J. No. 1 with ease.

---

[1] A paper read before the Clinical Society of Maryland, January 20, 1888.

There were still several other teeth in his mouth the nerves of which had been destroyed, and which were giving him considerable discomfort. One of these was a right upper molar, which had been filled in three places, and one of the fangs of which was exposed, at the side of the alveolar process, nearly to its extremity; and another was the left lower canine, which contained one filling, and was sensitive to pressure over its root. In addition to the disturbance in his vision, he had a great deal of headache, and pain at times in the facial branches of the fifth nerve. On March 1st these two teeth were removed by my advice, and this was followed by the immediate disappearance of the headache. Two weeks later the left pupil had regained its normal size, and responded fairly well to light, but with this eye he could, as yet, hardly read J. No. 4. However, a steady improvement now set in, and by April 5th the left eye could read J. No. 9, but only when it was held at about 16″ from the face. On May 1st it could read it at 7″, almost as close as the other eye, and the left pupil was now rather smaller than the right. On June 8th he reported that since his visit to me, six days before, the dentist had been treating another dead tooth (a left lower incisor), and had found it necessary to remove the filling from it, and that in consequence severe inflammation had ensued, accompanied by swelling of the face and a considerable amount of fever. Coincident with this attack, he observed that the right pupil became enlarged, and that his near vision grew less distinct. The dilatation of the right pupil was still quite marked when I saw him, but he was able to read J. No. 1 with each eye. I advised him to get rid of this tooth also, which he did; and a week later, when he paid me his last visit, the pupil was considerably smaller and the accommodation restored to its previous condition. It will be observed that after the discontinuance of the constitutional treatment, on January 5th, it was not again resumed, and that the recovery of the second eye took place without resort to any remedial measures, except the removal of the dead teeth.

At my request the patient was kind enough to call upon me (January 18, 1888), so that I might learn the present condition of his eyes. I found that he was still wearing, in near vision, the $+\frac{1}{36}$ c. glasses, which I had prescribed for him, and that with these he could read J. No. 1 with ease, with each eye, the near point for the left eye being 8″, for the right 7″, and the binocular near point being also 7″. The pupils were of equal size, and rather larger, when examined with the light from the window falling upon them, than is usually the case with normal eyes. They contracted and dilated in the usual manner with changes in convergence and accommodative tension, but to light stimulation neither would respond in the slightest degree.

About six months after his last visit to me (December, 1886), and coincident with the occurrence of irritation and tenderness about another of his dead teeth, the sight of his left eye, he told me, had again become affected, and the pupil enlarged. At this time he was induced to seek the advice of a specialist of great popular repute, who, according to the patient's account, made light of the dental-irritation theory to which I had attached so much importance, assured him that the degree of astigmatism (Ah. $\frac{1}{36}$) which he had was of no account, and advised him that he required no treatment except the selection of proper glasses. Thereupon he proceeded to determine what these were, and as a result of his tests, he prescribed for near vision: for the right eye, $+\frac{1}{48}$ s.; for the left eye, $+\frac{1}{15}$ s. Presumably, these glasses were intended to equalize the vision of the two eyes, the accommodation of the left being defective. However, as the difference between the accommodative power of the eyes did not long remain as it was when the glasses were prescribed, they, of course, soon became useless and were thrown aside, the cylinders being resumed, to be worn, as I have stated, up to the present time.

The two cases which I have related have interested me especially because, in some measure at least, they seem to me to afford evidence in favor of the older, and now generally discredited, view of the pathogenesis of sympathetic ophthalmitis, which, not long since, I had the temerity to attempt to defend.[1] Whatever may be said as to the conclusiveness of the evidence in Case I., that the ocular paralysis was really due to dental irritation, there is, certainly, in Case II. no room for doubt upon this point. We have, then, at least, one striking example of reflex ocular disease due to persistent irritation of a branch of the fifth nerve. That the direct cause of the ocular paralysis was not situated in the affected eye itself, but in some ganglionic centre back of it, there is, I think, little room for doubt; and such doubt as might exist upon this point seems to me to be dispelled by the decided effect upon the pupil and the ciliary muscle which was produced by the instillation of eserine. It is, perhaps, scarcely possible to locate with certainty this centre, but, at any rate, it does not seem *necessary* to go further back than the ophthalmic and Gasserian ganglia, in order to explain all the observed phenomena, including the impairment of the sense of taste; for in the former we have a connecting link between the fifth nerve and the third, and with those branches of the latter, especially, which supply the iris and ciliary muscle, and in the latter the gustatory nerve is, of course, in relation with the other sensory branches of the fifth. As to what was the exact nature of the changes which occurred in the centres involved, in consequence of the persistent irritation of the dental nerves, we are also not in a position to speak with certainty; but we are, I think, warranted in assuming, at least, that they were structural in character, rather than simply vaso-motor, from the slowness with which the ocular paralysis disappeared after the removal of the original source of irritation.

That there is a very close parallelism between the sequence of events which must have taken place in this case and that which occurs, according to those who believe that the disease is a reflex neurosis, in sympathetic ophthalmitis will, I think, scarcely be denied. In the one case we have, as a result of persistent irritation at the peripheral extremity of branches of the dental nerves, structural changes in ganglionic centres having connections with the fifth and third nerves, of such a character as to produce paralysis of certain of the ocular muscles, usually, it would seem, upon the side corresponding with the location of the diseased tooth. In the other we have, in the same way, in consequence of persistent irritation of the ciliary nerves (in the primarily affected eye), structural changes brought about in ganglia connected with the fifth nerve, some of which, at least, are central, and these, in turn, probably through the medium of vaso-motor or "trophic" nerves, leading to the development in the opposite eye of the condition which we call inflammation. The disciples of Cohnheim tell us that this is impossible; that their experiments prove that inflammation cannot be produced in this way. But are they justified in believing that they have reproduced, experimentally, essentially the same conditions that exist in sympathetic ophthalmitis? For one, I am not disposed to admit it.

---

FRACTURES THROUGH THE HEAD OF THE RADIUS.[1]

By CHARLES A. POWERS, M.D.,

SURGEON TO OUT-PATIENT DEPARTMENT, CHAMBERS STREET HOSPITAL, NEW YORK.

SIR ASTLEY COOPER[2] says, of fracture of the upper extremity of the radius: "I have heard it mentioned as of frequent occurrence, but there must be some mistake in the statement, for it is an accident which I have never seen, and if instances do present themselves (which I do not mean to deny) they must be very rare."

Hamilton,[3] speaking of fractures in this location, says: "While, therefore, the presence of what appears to be the rational diagnostic signs has compelled me to record one case as an uncomplicated fracture of the neck of the radius, and two others as fractures at this point, accompanied either by a fracture of the humerus or a dislocation of the ulna, I am prepared to admit that some doubt remains in my own mind as to whether in either case the fact was clearly ascertained. Nor do I think, speaking only of the simple fracture, that it will ever be safe to declare positively that we have before us this accident, lest, as has happened many times before, in the final appeal to that court whose judgment waits till after death, our decision should be reversed."

Stimson[4] says: "Our knowledge of this variety of fracture is drawn from about a dozen specimens, and two or three doubtful cases."

In view of the foregoing expressions of these well-known authorities, the following case seems worthy of record and study. Of one thousand and twelve cases of simple fracture of the radius treated at the Chambers Street Hospital during the past seven and a half years, it is the only one in which the head of the bone is noted as the seat of lesion.

H. S——, aged twenty-six, a native of Germany, a stout, muscular porter, fell about ten feet at five o'clock in the afternoon of March 24, 1887. Immediately thereafter he sought treatment at the Chambers Street Hospital, and upon examination the followingcondition was noted: Inspection of the injured elbow revealed only moderate swelling on its outer aspect, this due to the contusion. The patient could completely flex and extend the forearm, but said that this occasioned much pain. The forearm was pronated, and he was unable to supinate it. Fracture of the humerus or ulna was excluded by the usual process of examination, as was also fracture of the radius below its neck. On placing the thumb of the left hand on the head of the radius and rotating its shaft with the right hand, the head was felt to roll beneath the thumb, but a diffuse bony crepitus was both felt and heard. This manipulation occasioned very severe pain; pressure over the head of the radius also detected a deeply seated point of local tenderness. The inner half of the head could be fixed beneath the left thumb; then, on grasping the outer half of the head between the thumb and forefinger of the right hand and "rocking" the parts, the outer half was distinctly felt to move on the inner.

Diagnosis was made of fracture through the head of the radius, approximately from the middle of its cup-shaped articular surface downward and inward to the upper part of the neck.

The elbow was placed at a right angle, the forearm in a position midway between pronation and supination, and a plaster-of-Paris splint applied from the wrist to the upper third of the humerus.

This dressing gave rise to no disturbance, and was left in place for twenty-seven days, at the expiration of which time it was removed and the following condition noted: There was considerable thickening all about the outer aspect of the elbow, this obscuring accurate examination of the bony parts. The circumference of the arm at its middle was two inches smaller, of the elbow one inch larger, and of the forearm three-fourths of an inch smaller on the affected side than at the same points about its fellow. The patient could flex the forearm to eighty degrees, and could extend it to one hundred and twenty. Pronation and supination were almost *nil*. Movements at the joint occasioned no pain. He was directed to apply a flaxseed poultice nightly, to soak the joint in hot water morning and night, and to rub it thoroughly with neat's-foot oil after each hot bath. Flexion and extension quickly improved, and on May 17th, twenty-six days after the removal of the splint, the patient could almost completely flex the forearm, and could extend it to one hundred and sixty degrees. Pronation and supination, however, did not improve. He returned to his work as a porter, at which he has since been engaged.

His present condition, six and a half months after the injury, is as follows: The circumference at the middle of the arm on the affected side (the left) is one inch less than on the opposite; measurements about the flexed elbows show no difference, while at the middle of the forearm the affected side is half an inch smaller than its fellow. Flexion at the elbow is ten degrees short of normal; extension can be made to one hundred and sixty-five degrees.

The forearm is in a position midway between pronation and supination, and the radius at the wrist describes but one fifth of its normal arc about the ulna.

The external condyle of the humerus is slightly thickened and rounded. The head of the radius can be plainly grasped antero-posteriorly, and is fully half an inch broader than its fellow. On rotating the shaft the head is plainly felt to move, and postero-externally a prominent ridge of bone may be distinguished.

All movements at the elbow-joint elicit a diffuse, soft crepitus, which is present in a less degree on the opposite side.

The patient works daily at lifting heavy parcels, and says that he experiences no discomfort whatever, except that due to the limitation in range of pronation and supination, and this is comparatively trivial.

The recorded cases of this lesion are few in number and scanty in detail; in fact, they seem to have been presented only as surgical curiosities.

Stimson has collated eleven cases, and to these I have been able to add three, including my own, making fourteen in all. For purposes of comparison, I append a brief synopsis of each:

CASE I. (Malgaigne).[1]—Case observed by A. Berard in 1834, in which post-mortem examination revealed a fracture of the coronoid process of the ulna, together with an oblique fracture downward and forward through the head of the radius, severing about one third of its articular surface.

CASE II. (also cited by Malgaigne, seen by Velpeau in 1840).—A man, aged forty-five, sustained a dislocation of the forearm, which was at first mistaken for a contusion. At the end of six weeks, failing to regain the use of the joint, he consulted M. Velpeau, who recognized the condition, but tried in vain to reduce the luxation. The patient succumbed to an erysipelas, and the autopsy revealed the presence of a fracture through the coronoid process of the ulna, as well as a fracture through the anterior half of the head of the radius.

---

[3] Fractures and Dislocations, sixth edition, p. 299.

[4] Treatise on Fractures, p. 431.

[1] Traité des Fractures et des Luxations, vol. ii., p. 636.

CASE III.—Mr. Sampson Gamgee[1] relates a case in which a man, aged twenty-six, sustained a backward dislocation of the ulna, together with a fracture through the head of the radius. He does not state the direction of the fracture, or treatment adopted, but says that the case made a rapid and complete recovery.

CASE IV. (cited by Mr. Pick).[2]—A man fell from a scaffold, and died from fracture of the base of the skull. After death, a vertical antero-posterior fissure was found running through the centre of the head of the radius, separating one-half of the cup-shaped cavity and a small portion of the shaft from the rest of the bone. There was no other lesion, and the orbicular ligament was intact.

CASES V. AND VI. (specimens).—Seen by Hamilton in Dr. Mütter's cabinet. In one a small fragment from the outer part of the head of the radius was slightly displaced downward in the direction of the axis of the bone; in the other the fragment was thrown outward, or to the radial side. Both were firmly fixed in their new position.

CASE VII. (specimen).—Bryant[3] instances a case occurring in a woman, aged seventy, who fell on the elbow, breaking off the coronoid process and the anterior third of the head of the radius. The specimen is in the museum of Guy's Hospital.

CASES VIII. AND IX.—Holmes[4] mentions a case in which both forearms were dislocated backward, both coronoid processes broken, and the head of each radius split longitudinally.

CASE X.—Hodges[5] presented to the Boston Society for Medical Improvement a specimen showing a clear and regular split through the head of the radius involving very nearly one-half, and clearing outward so as to extend no farther than the neck of the bone. It was associated with an oblique fracture of the shaft of the ulna, commencing above at the constriction between coronoid and olecranon, and extending three and one-fourth inches downward, detaching from the shaft that portion of bone to which the olecranon was attached.

CASES XI., XII., AND XIII.—Stimson[6] instances three cases observed by himself. Case XI.: A boy, aged thirteen, admitted to the Presbyterian Hospital, March, 1877, with suppurative arthritis of the right elbow, following a blow received two months before. Dr. Stimson excised the elbow, and in the course of the operation found the outer half of the head of the radius separated from the rest and from the shaft, with an irregular surface of fracture and preservation of the articular cartilages. Case XII.: Man, aged twenty-seven, admitted to the Presbyterian Hospital in April, 1882, with backward dislocation of right elbow. Dr. Stimson reduced the dislocation under ether, and then felt a movable piece of bone on the outer side between the olecranon and the head of the radius; he removed it under antiseptic precautions. It was a part of the head of the radius, presumably from the upper and inner aspect, about one-third. Of this case Dr. Stimson[7] says: "I met this man, May 24, 1883, at which time flexion and extension were almost complete, but rotation was entirely lost. The forearm was in a position midway between pronation and supination, and the patient said that it was strong and serviceable." Case XIII.: A case seen by Drs. McBurney and Yale in Bellevue Hospital in 1881. The patient was a muscular man, thirty-nine years of age, who fell from a ladder, striking on the outer side of the left arm, which was held close to the body. After the swelling had subsided, a movable piece of bone could be felt at the side of the head of the radius; crepitus could be felt when the wrist was rotated. Dr. Stimson saw the patient in 1882, at which time flexion of the elbow was complete, extension amounting to one hundred and forty degrees, and pronation and supination limited to ninety degrees.

The head of the radius was irregular, its diameter greater than usual, and the distance from its upper edge to the top of the olecranon nearly an inch greater than on the right side. The arm was useful and strong, and the patient on duty in the Fire Department.

The fourteenth case forms the subject of this paper. Of these fourteen cases, eight were complicated either by a fracture through some portion of the ulna or by a dislocation of the forearm; three are pathological specimens without history, and one was discovered during an operation for suppurative arthritis of the elbow. There were but four cases in which a diagnosis was made, and treatment adopted, and of these four only two were uncomplicated.

Assuming, then, that fracture through the head of the radius, though a very rare lesion, is yet of undoubted occurrence, what are the evidences on which a diagnosis may be based?

I feel that there is but one, namely, a movable fragment of bone. Joint-crepitus about the elbow is particularly deceptive, and we know how frequent are those cases which present the harsh, grating sound characteristic of fracture, but in which most thorough examination under an anæsthetic fails to assert the undoubted presence of a bony lesion. If one assuredly obtains a false point of motion between the fragments of the head of the radius, there must be a solution of continuity in the bone itself; failing of this, he cannot feel assured that there is a fracture, for minor evidences, as local tenderness, disability, pain, swelling, and ecchymosis accompany most cases of severe contusion. Hutchinson[1] thinks that the click, characteristic of the partial downward dislocation of the radius (by elongation), is often mistaken for evidences of fracture.

Hodges[2] says that fracture through the head is more common than is thought, but, from the non-displacement of the fragments and the difficulty of diagnosis, fails of recognition.

As to prognosis, Gamgee states that his patient made a rapid and complete recovery, and by this we assume that all of the functions resumed their normal condition; but in the other three cases—McBurney's, Stimson's, and my own—the functional results are almost precisely similar; namely, good flexion and extension, but very limited rotation.

The smaller fragment can be nourished only by absorption and by the spread into it of granulations from the layer, yet those of us who have had the fortune to deal with compound fractures of the head know how very vascular it is, and we may be assured that if the fragments are apposed and kept at rest, there is but little danger of non-union.

In my own case, I think the limitation of rotation of the head in the lesser sigmoid cavity due to the presence of a considerable callus, both anteriorly and posteriorly, which acts as a mechanical impediment, and I should think that in all cases (except, possibly, those in which a small fragment is chipped off the outer aspect) the callus would restrict rotation in this way. In this event the range of motion should improve with time.

There is but little to be said regarding treatment: The best possible apposition of the fragments, the forearm at ninety degrees, midway between pronation and supina-

tion, and fixation in this position by some such apparatus as the plaster-of-Paris splint. At the expiration of four weeks union will very probably obtain, and the splint may be discontinued and the joint subjected to the usual course of hot baths, massage, and action.

Clinical Department.

A CASE OF DEATH BY SUFFOCATION IN PHLEGMONOUS TONSILLITIS.

By JOE HOWELL WAY, M.D.,

WAYNESVILLE, N. C.

While most, if not all, writers on the subject of tonsillitis admit the possibility of the occurrence of sudden death from rupture of the tonsil and escape of pus into the larynx, the accident is one of such extreme rarity that the possibility of its occurrence is often forgotten. So far as I have been able to ascertain from the limited medical literature at hand, I find recorded only two cases where death has resulted from this accident, occurring during sleep, and one in which it took place while the patient was awake and in the act of speaking. To these three cases I desire to add a fourth, which has recently occurred under my own observation.

On November 7th I was consulted by G. H. M——, a merchant, aged twenty-four, of stout, plethoric build and of scrofulous diathesis, who has been an occasional patient of mine for the past two years, during which time he has had several attacks of bilateral phlegmonous tonsillitis. On two occasions the swelling was so great that I deemed it advisable to incise freely each tonsil and permit the pus to escape. At other times the treatment consisted, in the main, of the internal exhibition of guaiacum, aconite, and quinia, with the local application of iodo-tannin, and frequent gargling with hot water. Mercurials were usually administered early in the attack. The attacks usually subsided in from five to eight days, during most of which time the patient was attending to the duties of his store. At the time of my examination, on November 7th, I diagnosed phlegmonous tonsillitis, and adopted the plan of treatment indicated above, which I had found efficacious in previous attacks. After this, though feeling quite unwell, he remained in his store until the afternoon of November 10th, when he consulted me again, complaining of a throbbing, pulsating sensation in the region of the tonsils, and also of pain in the ear. Examining his throat, I found each tonsil very much inflamed, and swollen so as to touch at one point in the mesial line. I thrust a small bistoury boldly into each tonsil, and from the left fully three drachms of pus exuded, with the result of greatly reducing the swelling on that side. From the right tonsil only a small amount of blood came, and no pus. These incisions seemed to afford much relief. My patient complaining of being unable to procure sleep by the aid of the hypnotics that I had prescribed for him, I visited him about 9 P.M. and administered a hypodermatic of morph. sulph. (gr. $\frac{1}{8}$) and atrop. sulph. (gr. $\frac{1}{120}$).

On the following morning I visited him, and found the tonsils swollen about as badly as on the previous afternoon, prior to my incising them. He reported himself as having been able to sleep some during the night, though not so well as he should have liked. His temperature was 102.6° F.; pulse, 96; and general condition as good as usual in similar attacks. I applied iodo-tannin to the inflamed glands, and also an emollient poultice to the neck over the situation of the tonsils. The quinia and gargles were also continued, and the patient was advised to remain in bed. At 10.30 P.M. I visited him again, and found him in about the same condition as in the morning. His pulse was 94; temperature, 102°; he had been able to take some fluid nourishment during the day, and said he believed he would be able to get out on the morrow, if he could only get some sleep.

His throat presented much the same appearance as in the morning. I again administered the hypodermatic of morphia (gr. $\frac{1}{8}$) and atropia ($\frac{1}{120}$), as on the previous evening, and a few minutes later retired to a room on the same floor of the building, two doors removed from the patient. An hour and a quarter later I was hastily summoned to attend my patient by a gentleman who was occupying the same apartment with him. His tone betokened alarm, and without dressing, or waiting to question him, I hurriedly repaired to his room. My patient was dead! Intravenous and intracardiac injections of ammonia, with artificial respiration practised more than half an hour, failed to elicit at any time the slightest evidences of vitality. Examination of the body of the deceased revealed the fact that the upper pharyngeal region and the larynx, especially the latter, contained a large quantity of pus and broken-down tonsillar tissue, derived from the rupture of the right tonsil. There were no evidences of cardiac or renal disease; *per contra*, the deceased had always, saving the frequent attacks of tonsillitis, enjoyed excellent health.

From his companion I learned that within fifteen or twenty minutes subsequent to my departure he had sunk into a peaceful slumber, breathing quietly and without any difficulty for almost an hour. He then seemed to stop breathing for a moment, but soon made one or two ineffectual gasps for breath, which so alarmed his companion that he rushed out of the room and down the hall to my room. In not more than one minute from the first respiratory difficulty I was at the bedside, but the life-principle was then entirely extinct.

GALL-STONES OR SOAP?

Dr. A. Noel Smith, of Dover, N. H., writes: "I noted an article in The Medical Record of January 14th, taken from the *Lancet*, in which Dr. Just Tonatu, of New Orleans, advocates olive-oil in large doses for cure of hepatic colic. A bit of my own experience was at once called to mind, and I could not help thinking that Dr. T—— might have been mistaken in some of his conclusions. As I understand it, there has existed for some time a popular idea, more or less diffused, that very full doses of sweet-oil would relieve in cases of gall-stones, for they have 'seen the stones.' And so they have; some things having the *appearance* of gall-stones, but which, if examined critically and carefully, would be found not to be such.

"A case to the point: I was invited by a good lady to step into her house one morning to see a display of gall-stones which she had succeeded in bringing away from her husband by the use of olive-oil. She had carefully washed the discharges, and separated these greenish oval bodies, and had them all spread out upon the floor, to the number of fifty or sixty, varying in size from a pea to a nutmeg. I carried some of the best specimens to my office, and, together with two other physicians, looked them over. They were of a soapy feel, readily crushed under the finger, and of similar consistence throughout. We could find no semblance of a stone in any of them, and came to the conclusion that they were only saponaceous masses, formed from the presence of excess of oil, and I so informed the family. We were confirmed in the above opinion by the following statement, which may be found on page 1076 of the 'National Dispensatory' by Stillé and Maisch, and bearing directly upon the subject in hand:

"'A notion has been entertained that large doses of olive-oil were capable of causing the discharge of gall-stones, and in proof of the statement a great number of bodies resembling these concretions has been found in the stools. On examination, however, they were found to consist of the partially saponified oil.'"

Progress of Medical Science.

RESECTION OF LEFT LOBE OF LIVER.—Dr. Langenbuch (*Berl. Klin. Woch.*, 1888, No. 3) records a case in which he successfully resected the greater part of its left lobe, which had been extensively deformed by tight lacing, and had caused great inconvenience and trouble to the patient. The woman, about thirty years of age, was, in November, 1886, under treatment for erysipelas at the Lazarus Hospital, and when about to be discharged convalescent, she begged that she might be relieved of a painful abdominal tumor that rendered life unbearable, and caused pain both on standing and on lying down. On examination a tumor of the size of the fist was detected in the epigastrium—dense, elastic, not fluctuating, moving with respiration, and its dulness continuous with that of the liver. The diagnosis lay between hydatid tumor and deformity from tight-lacing (*Schnür-leber*), although the latter condition usually involves the right lobe. An exploratory incision proved that the case was of this kind, but involving the left lobe, and probably for that reason producing the painful symptoms. Dr. Langenbuch decided that it would be advisable to remove the source of so much distress, especially as the portion of the lobe forming the tumor was practically cut off from the rest of the organ by a broad but ligamentous pedicle, and therefore it was functionally of no service. Accordingly, the pedicle was transfixed by ligatures, and the lobe excised. The same evening symptoms of severe internal hemorrhage appeared, and, on reopening the wound, the abdominal cavity was found to be filled with blood; this was sponged out, the bleeding vessels secured, and no further trouble arose from that source. The wound healed, but recovery was somewhat retarded by the development of ascites, which necessitated tapping on two occasions. It could not be determined how far the ascites was due to the cardiac debility and hydræmia resulting from the previous prolonged attack of erysipelas and the profuse hemorrhage, or how far it might have depended on the diminution of the hepatic circuit. There was œdema elsewhere, so the former hypothesis had some support. At any rate it was not permanent, and the patient left in February quite well. The portion of liver removed weighed three hundred and seventy grammes (about twelve ounces), and Dr. Langenbuch says that the case shows the feasibility of removing the lobe of a tight-laced liver when this gives rise to serious discomfort.—*Lancet.*

PARALYSIS OF THE ABDOMINAL MUSCLES.—At a meeting of the Paris Société de Chirurgie, Dr. Deprès exhibited a photograph of a woman whom two medical attendants had believed to be subject to ovarian disease. The abdomen was extremely pendulous, and measured forty-eight inches round the umbilical level (*The British Medical Journal*). On careful examination, Dr. Deprès found that the abdominal muscles were entirely paralyzed. The patient could not rise from her bed without supporting the abdomen with her hands. No contraction of the muscles occurred during movement or coughing, nor under any form of electrical stimulation. Frequent pregnancies often cause distention, thinning, and consequent weakening of the abdominal muscles, but never paralysis. His patient had been only twice pregnant, and the labors were normal. Lannelongue stated that he had seen paralysis of the abdominal muscles in anterior poliomyelitis, but without the symptoms noted in Deprès' case. Marc Sée believed that pendulous abdomen was certainly most frequent among multiparæ, but had been observed in women who had only borne one child. Dr. Deprès replied that he had seen numerous cases of pendulous abdomen which simulated ovarian disease, but never, before this example, any instance of paralysis of the abdominal muscles which had caused symptoms mistaken for those observed in cystic tumors of the ovary. Pendulous abdomen is a well-known affection. Landau has recently written an able treatise on its nature and treatment, and its due recognition is of importance to physicians and surgeons, as well as to obstetricians. A cursory glance or sweep of the hand over a pendulous abdomen may give rise to a serious error of diagnosis. Ascites, pregnancy, ovarian or uterine tumor, may be suspected, especially when the walls are very thick, so as to interfere with resonance on percussion. In cold weather, or when the hand of the observer feels chilly, contractions of the recti are set up, and may give the erroneous impression that some solid growth is present. The support of a belt gives comfort, and to a certain extent cures the affection. Mr. Treves has recently declared that the belt is not advisable after ovariotomy and allied operations, as it interferes with the natural process of recovery which the muscles, weakened by long distention, would undergo if left to support themselves. However, many experienced authorities would dread the abolition of the abdominal belt after abdominal section, for hernia of the cicatrix is not rare. Indeed, Dr. Homans, of Boston, discovered that it ultimately developed in ten per cent. of his patients, and those who are as careful about after-histories as Dr. Homans would possibly find their proportion just as high. Thus the question of the means of making the abdominal walls as strong as possible after an operation becomes very important, and the relative merits of Mr. Treves' principles and the usual practice deserve consideration. The case of true paralysis of the abdominal muscles described by Deprès must not be overlooked, since it is a condition which we may safely say has been frequently confounded with a simple pendulous condition of the abdominal walls.

STIMULANTS TO BE AVOIDED IN THE TREATMENT OF SKIN DISEASES.—In an article on diet in cutaneous affections, by Dr. G. H. Fox, the following suggestions occur: One very important point to be considered in preparing a diet list for patients with skin disease is the effect of alcohol, tea, coffee, and tobacco in retarding tissue-metamorphosis. To improve the nutrition of the skin, it is desirable that the processes of waste and repair be carried on without cessation. When alcohol or other stimulants are consumed to any extent, this desirable change or reconstruction of tissue is arrested, and the various organs of the body are impaired in the performance of their functions. The effect of beer upon an eczema is as marked as it is upon a gonorrhœa. Dr. Fox has sometimes thought it better for a patient to drink a whole bottle of whiskey than a single glass of malt liquor. In cases of pruritus, in private practice, the author has fallen into the habit of forbidding all stimulants, on the ground that they do no good and may do harm. In charity practice it has often struck him as the height of folly to prescribe medicine for patients who are living largely on tea and beer, and whose symptoms would speedily disappear under a judicious regulation of diet. Indeed, it is difficult to appreciate what dietetics will do in the treatment of cutaneous and other diseases unless we move, for the time being, a suspension of the Pharmacopœia.—*The Dietetic Gazette*, January, 1888.

POISONING BY HYOSCYAMIN.—Dr. Johnson, of Toronto, recently met with a case in which one-twelfth of a grain of hyoscyamin produced most alarming symptoms. Having investigated the subject, he has reached the following conclusions: 1. Poisoning by hyoscyamin resembles, and may be easily mistaken for, poisoning by atropine. 2. Hyoscyamin is identical with "light atropine," "light daturine," and "duboisine." 3. There are various preparations known as "hyoscyamin." 4. These preparations differ exceedingly in their strength. 5. There is a pure alkaloid hyoscyamin which should not be given, at first, in more than $\frac{1}{100}$ of a grain doses; and 6. There is a resinoid hyoscyamin, commonly dispensed as "hyoscyamin," which may be given in doses of $\frac{1}{4}$ to one grain.

7. It is advisable for the safety of our patients, when prescribing hyoscyamin, to name the manufacturer whose drug we wish used.—*The Canadian Practitioner*, January, 1888.

THE ADDITION OF AN ACID TO CORROSIVE SUBLIMATE SOLUTIONS TO INCREASE THEIR ANTISEPTIC POWER.—Dr. E. Laplace has made a series of experiments in order to determine whether sublimate dressings, such as gauze, cotton, rollers, etc., were really aseptic (*i.e.*, free from microbes) and antiseptic (*i.e.*, germicidal).

He found that while most of the dressings were aseptic, none of them exerted positive antiseptic powers. It has been proven by numerous investigations that when the sublimate solution is brought in contact with albuminous fluids, an insoluble albuminate of mercury results, which is entirely devoid of antiseptic properties. This takes place when sublimate dressings are applied to the body, and explains the poor results obtained from their use in some cases. Laplace found that the addition of an acid to the sublimate will prevent this coagulation. He especially recommends tartaric acid.

The following are his conclusions:

1. Acid solutions of corrosive sublimate exert the full effects of the drug even in albuminous fluids.
2. The combination of an acid with the sublimate increases its antiseptic powers, so that weaker solutions are required.
3. The acid sublimate dressing does not interfere with the employment of other measures—caustics, iodoform, etc.
4. The acid sublimate solution and gauze gives more satisfactory results in the laboratory and in practice than other disinfectants.
5. The wounds are not irritated.

The solution employed by Laplace is the following:

Sublimate	1.0
Acid. tartaric	5.0
Aq. destil	1,000.0

Gauze, cotton, etc., are soaked for two hours in a solution of:

Sublimate	5.0
Acid. tartaric	20.0
Aq. destil	1,000.0

The author obtained very satisfactory results with this dressing in the treatment of suppurating wounds. The fetor rapidly disappeared, granulation was established, and the dressings remained sterile, in one case for six days.—*Deutsche Med. Wochenschrift.*

THE RESULTS OF OPERATIVE INTERFERENCE IN ACUTE INTESTINAL OBSTRUCTION.—B. Farquhar Curtis, M.D., of New York, in a paper read before the Medical Society of the State of New York, presented an exhaustive *resumé* of the results of operative interference in acute intestinal obstruction. Statistics founded upon 339 cases of *true* laparotomy for *acute* obstruction gave a gross mortality of 68.4 per cent.; intussusception, seventy-six per cent.; volvulus, eighty-two per cent.; adhesions, sixty-six per cent.; bands, fifty-nine per cent.; internal incarceration, sixty-one per cent.; stricture, forty per cent.; tumors of the gut, seventy-four per cent.; foreign bodies, sixty-seven per cent.; miscellaneous, ninety-one per cent.; undetermined, sixty per cent. The mortality for operations performed in the first twenty-four hours after onset of the symptoms is sixty-two per cent.; in the second, seventy per cent.; in the third, seventy-three per cent.; but after that there is no regular variation in the percentage, because the operation was delayed in every case until the patient was reduced to about the same state of exhaustion. The most frequent cause of death was the bad condition of the patient, owing to the delay usually allowed in these cases. Out of the 232 fatal cases, in 103 the condition of the patient is described as bad, while the complicating peritonitis and gangrene of the gut found on operation in 28 others showed that the operation was delayed too long. In 20 cases the cause of obstruction was not found, and in 10 it was irremediable. Of deaths directly traceable to the operation there are only 45, 17 due to sepsis, 13 to shock, and in the rest death was probably due to shock and exhaustion. A very important factor in the mortality is the duration of the operation. When the obstruction could be removed without wounding the gut the mortality was only fifty-six per cent.; when it was necessary to establish an artificial anus (the obstruction being removed) it was seventy-three per cent., and when the gut was sutured, whether in its entire circumference or not, the mortality rose to eighty-three per cent. Although enterotomy (including colotomy) was for so long a time considered superior to laparotomy in the treatment of intestinal obstruction, it is better suited for, and more often resorted to in, the more chronic forms. Of late there has been a revival of interest in the operation, owing to the bad results of laparotomy; but in spite of this fact the published observations are not yet numerous enough to allow of very satisfactory statistical study, and for the present we must be content with the figures given by Treves—61 cases with a mortality of sixty-seven per cent. As enterotomy only relieves the symptoms and does not remove their cause, the mortality must be much reduced in the future before it can be placed upon a par with laparotomy as a method of treatment for acute intestinal obstruction.

STONE IN THE STOMACH.—Concretions, or stones, are not often found in the human stomach, though the bezoar of the abomasum and intestines of ruminants is well known, and in olden days was very highly esteemed as a remedy against poisons and infectious diseases, being even worn as a charm. Human intestinal agglomerates are occasionally found in oatmeal-eating districts, and have sometimes been dignified by the name of "avenoliths." An enterolith was found by Laugier in a human subject, the nucleus of which was formed by a piece of liquorice root. True gasteroliths are, however, occasionally found in human stomachs; thus Schönborn was able to collect seven such cases, all of which appeared to have formed round a nucleus of hair; one of these weighed two kilogrammes. Quite recently a Dutch physician, Dr. H. A. Kooyker, has described a case of true gastric concretion weighing 885 grammes, in which there was no nucleus at all. The patient was a middle-aged man, who was so averse to examination and manipulation of all kinds that it was very difficult to form a diagnosis of his disease. He occasionally vomited blood, and gradually became more and more emaciated. A tumor was felt in the epigastrium, but its nature was not made out until the post-mortem examination revealed a stone measuring eighteen by eight centimetres, nearly filling the cavity of the stomach. There was also a smaller stone, situated at the pyloric extremity. These stones were of a brownish color, and the large one contained several cavities. It had an offensive smell like that of fæces. A number of vegetable cells were found in it, but it was devoid of concentric or other structure. It does not seem to have been fully analyzed.—*The Lancet.*

OLIVE-OIL IN BILIARY COLIC.—Dr. Herman Ostrander, of Lansing, Mich., reports the following case of self-cure of biliary colic which was related to him by a young architect of that city. The gentleman's mother, who was a great sufferer from gall-stones, took, during one of her attacks, half a tumblerful of olive-oil, and repeated the dose in twenty-four hours. The result was the painless passage of more than forty calculi. On the occurrence of another attack, about a week later, she repeated the treatment and passed more than sixty calculi. Since that time she has been entirely free from these attacks, although several years have since elapsed.

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

GEORGE F. SHRADY, A.M., M.D., EDITOR.

PUBLISHED BY
WM. WOOD & Co., Nos. 56 and 58 Lafayette Place

New York, February 25, 1888.

THE ACIDITY OF THE GASTRIC JUICE, AND THE DIAGNOSTIC VALUE OF ITS VARIATIONS.

THE numerous observations which have been made, almost exclusively by German physicians, on the acidity of the gastric juice, and, in particular, the percentage of free hydrochloric acid in it, have produced important physiological and clinical results. Our readers will be interested, therefore, in a review of some of the more recent work in this line, work which deserves to be undertaken in this country to a greater extent than has yet been done.

The general facts claimed, with regard to the variations in the acidity of the gastric juice, are that in gastric cancer free HCl is absent; in other chronic gastric disorders it is diminished, increased, or unchanged, according to the nature of the trouble.

While Riegel, Kahler (*Prag. Med. Woch.*, Nos. 32 and 33), and others have examined a large series of cases of gastric cancer, and found no free HCl, even in early stages of the disease, Petersen (*Verhandl. des XVI. Congr. des Deutsch. Chur.*, 1887), and Cahn (*Verhandl. des VI. Congr. für inn. Med.*, Wiesbaden, 1887), have reported a few cases in which this acid was present in this disease. Dr. F. Spaeth also reports cases illustrating both its presence and absence. The last-named physician has devised a very simple apparatus for testing the presence or absence of HCl. He takes a small bullet, calibre No. 6, and wraps about it a silk thread, No. 1, which has been previously soaked in a 0.015 per cent. watery solution of Congo red. To this is fastened also a small piece of elder pith which has been soaked in blue litmus paper. The whole is attached to a long silk thread. The bullet and pith ball are swallowed and allowed to remain in the stomach for a minute, then drawn up. Any acid present turns the litmus pith to red, while if free HCl is present it turns the Congo-red thread blue. The other ordinary color-tests for HCl are methyl violet, which is turned blue with feeble solutions, green with stronger solutions, of the acid; thin solutions of red fuchsin are turned yellow; solutions of tropæolin are turned from red to brown. A strong solutions of lactic acid may effect the same change in the above agents. Uffelmann gives the test with a chloride of iron and carbolic acid mixture: ℞. Sol. acid. carbol., ten per cent., ʒ ijss.; aquæ destillat., ʒ v.; neutral liquor ferri chlorid., ♏j. This solution, Congo red, is decolorized by free HCl, made yellow by lactic acid, gray by fatty acids, is turned blue by free HCl, but not by organic acids. Only, accordingly to Wurster (*Centralbl. f. Phys.*, 1887, I., No. 11), there must be no free ammonia or ammoniacal salts present.

Several observers have of late contributed the results of their observations upon the acidity of the gastric juice.

Dr. A. Kirstein, assistant at Professor Rossbach's clinic at Jena, reports (*Thüringer Korrespondenzblätter*, No. 8, 1887) the case of a man who appeared to be suffering from gastric cancer. The contents of the stomach were examined repeatedly, on different days and at different hours, and the methyl-violet reaction to HCl was plainly obtained; yet after death the autopsy showed the presence of a gelatinous carcinoma of the mucous membrane, with metastatic nodules in the perito neum.

Cahn and v. Mering found that in close titarmetric examinations of the stomach acids in pyloric cancer, that the presence of HCl was the rule, its absence the exception. They also denied the usefulness of the methyl-violet reaction test, and of that of Congo red, 39 = 47, 49 — 52.

C. Honigmann and C. v. Noorden (*Zeitschr. f. klin. Med.*, Bd. xii., H. 1) confirm the accuracy of Cahn and v. Mering's titrate method, but deny that the acid found was free HCl, since it possessed no peptic strength. The acid reaction was due to acid compounds, and they claimed that the small amount of HCl secreted in gastric cancer united with albumen compounds and was absorbed. They assert, as against Cahn and Mering, that the absence of the color reaction in gastric cancer was due to absence of free HCl. In fine, they uphold the value of the color-reaction test and of its significance in the diagnosis of cancer.

Dr. J. Grundzach examined the stomach contents in several hundred patients, and in five cases detected a constant absence of hydrochloric acid. Even in the course of digestion the stomach never contained HCl, and it reacted either neutral or feebly acid. In one case this acidity was due to lactic acid. There was a great deal of mucus secreted; the morbid condition was apparently that of catarrh. The muscular power and movements of the stomach seemed to be unimpaired.

In the same journal with Grundzach's paper (*Berlin. klin. Wochenschr.*, No. 30, 1887), Dr. L. Wolff and Professor Ewald report eight cases of entire absence of free HCl from the gastric juice, partly in healthy persons, partly in persons with some slight stomach disturbance. They found also that after these persons were given ʒ ss. of dilute muriatic acid the tests for the acid in the gastric juice still showed its absence. They conclude that HCl may be absent in tests from the stomach in perfectly healthy persons; that this acid may be absent in diseases which are not of a carcinomatous nature. Ewald seems to regard the absence of free HCl as an important clinical fact in gastric cancer, but not as an essential diagnostic sign.

Dr. von Sohlern, of Kissingen (*Berlin. klin. Wochenschr.*, 1887, p. 947), made a long series of experiments in order to determine the normal percentage of HCl in the stomach. This has been done before, but the subject was gone over with especial care. The persons examined were fed with the same amount and kind of food, the stomach contents were examined three hours, and in some cases five hours, after the meal. The results gave an average of 0.22 to 0.28 per cent. of pure hydrochloric acid in the gastric juice of healthy persons, after meals. These figures are lower than those of Ewald and Szabo, but higher than those of Riegel. The latter experimenter, however, made his examinations five hours after ingestion of food, which will explain the discrepancy. They are a little higher than the average usually given, viz., 0.2 per cent.

The method employed by Sohlern was the ordinary one of titration. He thinks that we may look upon this percentage, 0.22 to 0.28, as the normal average, subject to some physiological variations, like the specific gravity of the urine, but not departed from markedly or continuously except from disease.

Dr. Sohlern having determined the normal average, proceeded to make further investigations in cases, first, of chronic gastric catarrh. Each patient was given the same "test meal" of soup, beefsteak, and rice, three hours after which the stomach contents were examined. In twenty-one cases the per cent. of hydrochloric acid was below the normal, ranging from 0.12 to 0.19. In one case only was there excessive acidity. The clinical fact is established, therefore, according to Dr. Sohlern, that in gastric catarrh there is a diminished secretion of free hydrochloric acid. With improvement the gastric symptoms cause increase in the percentage of acid.

In almost all cases there was some lactic acid present.

In fifteen cases of gastric ulcer, twelve of whom had given a history of hemorrhage, there was an increase in the percentage of hydrochloric acid except in one instance. This patient had been greatly reduced by frequent copious hemorrhages. The increase in percentage was from 0.29 to 0.41, it being on an average about double the normal amount. These observations are in harmony with the observations of Riegel, and are certainly of great importance.

The patients examined were persons whose age ranged between twenty and thirty-two years; eight were women, seven were men.

In six cases of gastric dilatation there was a diminution of the per cent. of acid, ranging from 0.08 to 0.17. Naturally some of these cases were complicated with catarrh, and the same condition as regards the acid secretions would be expected.

Twenty-five cases of nervous dyspepsia were examined. They were cases in which there was a general neurasthenic state, with evident irritability and hyperæsthesia of the gastric apparatus. In all instances the percentage of HCl was found to be normal. Sohlern's observations confirm, therefore, the opinion of Leube, that in nervous dyspepsia all the phenomena depend upon disturbance of the nervous mechanism, and its abnormal excitability.

No opportunities were had of investigating the condition of the stomach in gastric cancer.

A NEW TREATMENT FOR BOILS AND CARBUNCLES.

THE ordinary methods of treating boils and carbuncles by a "free, bold incision" often leads to good results, but the anticipation of this cutting is always such a terror to patients that surgeons would most gladly use a milder treatment, if certain that cure would follow. M. Verneuil, with an experience of half a century, has noticed with interest the different phases through which the treatment of these painful maladies has passed. Following in the footsteps of his teachers, he freely used the knife, to give it up only when the thermo cautery came into use. Cauterization, with subsequent application of carbolated dressings, gave him such good results that his rule was to use the knife only exceptionally, in the gravest cases, and then to use it unsparingly. In 1883 he observed a case which made him reflect and change his mode of treatment. Since that time he has confined his treatment absolutely to the application of carbolated powders, and these for all kinds of boils and carbuncles, large, small, diabetic, painful or indolent, closed or open, and covered with gangrene. For the small and medium-sized carbuncles, this method of treatment has been very successful, without pain or extension of the inflammation.

In a communication to the French Academy of Medicine, at a recent meeting, he says: "This mode of treatment, so simple, has shown itself superior to all others in causing the sufferings, supportable but none the less disagreeable, to cease quickly, and in promptly limiting the trouble—a thing which cannot always be guaranteed in advance." After citing a number of facts to prove this statement, he concludes as follows:

"1. The furuncle and carbuncle are only degrees of the same infectious disease, and should have the same therapeutic treatment.

"2. This consists of surgical interference and topical applications. The former often seems indispensable, or at least only suitable for the majority of cases; the latter particularly efficacious in mild cases, but only playing a subordinate part in the treatment.

"3 The opposite should be accepted to-day. Cutting should become less and less necessary, and should be reserved for the exceptional cases. On the contrary, topical applications (prominent among which stand the carbolated and borated solutions) employed in a certain way, and particularly in the form of powder used repeatedly and for a long time, are of remarkable efficacy, and at the same time are absolutely harmless and easy of application.

"4. These applications of powder quickly abort, with very few exceptions, boils and carbuncles. They arrest the progress of the disease in the gravest cases, ordinarily cause the pains to quickly cease, reduce the fever, disinfect the purulent and gangrenous centres, hasten resolution, and promote the formation of healthy granulations.

"5. This treatment is suitable for all regions, and for all forms and periods of the disease; it is never harmful, and leads to a cure in a large number of cases. It assists surgical interference when that is necessary.

"6. Finally, it tends to prevent auto-inoculation and general infection."

In this report it is seen that the Frenchman is nothing if not enthusiastic. This treatment, however, is exceedingly simple, and bearing as it does the endorsement of such a man as M. Verneuil, should be carefully tried, even by the most incredulous.

STOMACH-WASHING IN CHILDREN.

To wash out the stomachs of adults has, for a number of years, been practised extensively, since Kussmaul first proposed it for the treatment of various gastric disturbances. In spite of the decided value of this mechanical treatment of the stomach, apparently but few practitioners have given it a fair trial. The reason for this may be looked for in the fact that it is a procedure requiring more energy on the part of the patient than skill of the doctor, the swallowing of the tube, in the first attempts, being usually attended by wrenching and even vomiting, besides taking up considerable time.

The unpopularity of this therapeutic measure for adults, among practitioners, also explains why its application in the treatment of children is almost unknown, though Professor Epstein, of Prague, as early as 1880, had fully demonstrated its applicability and usefulness (*Prag. Med. Wochensch.*, 1880, No. 45). In spite of repeated publications and reports on this subject, however, the great majority of physicians having charge of children's wards in hospitals and of clinics have either entirely overlooked them, or at once made up their minds that the infantile stomach-tube was the toy of a specialist desirous of the inventor's fame, and even considered its application a rather dangerous measure. All of these authorities, however, never tried this method themselves on children. Not until lately did this question loom up again in the pediatrical literature of Germany, when a few adherents of stomach-washing published extensive reports (Epstein: "Jahrb. f. Kinderk.," Bd. 27, 1888; Lorey: *Ibidem*, Bd. 26; Ehring: *Ibidem*, Bd.27; and Demme: "Jennersches Kinderhospitalbericht," 18, p. 89, Bern).

The method is the following: All clothing pressing upon thorax and abdomen of the baby are removed, the child is placed on the mother's lap in a half-reclining posture, and the head held forward. While gently pressing down the tongue with two fingers of the left hand, the operator slowly introduces a soft catheter (No. 8 to 10 of Jaques' patent, according to age). Irrigation is then proceeded with in the usual manner, always using *small* quantities of warm water, or boric solution (1 to 100) at first. The procedure is repeated until the water returns perfectly clear.

The indications are said to be: 1. Mild forms of dyspepsia in very young children (two to six weeks old), retarding their growth and laying foundations for future serious troubles. In these cases a single irrigation is said to cure the trouble. 2. In acute gastro-intestinal catarrh of summer, and in the most violent forms of cholera infantum, this remedial procedure is stated to have saved many lives, particularly when applied *early*, stopping the most obstinate vomiting immediately, and cleaning the stomach so as to take away all remnant of decomposed food lodged between the folds of the mucous membrane, and any organic or chemical poison which may have been the cause of the attack from the outset. 3. In cases of obstinate intestinal catarrh and enteritis, the mechanical cleansing of the stomach (together, here, with enemata) will act like the washing out of an abscess, as the contents of this organ, especially in such cases, are often of fetid and decomposed character, remaining in there for days and infecting all food put into the stomach, and sending to the intestines colonies of infectious material, keeping up the disease of the bowels. One or two washings often cure the case.

In Epstein's clinic, five thousand children were treated by this method with unusually good results. As the rationality of this therapeutic measure is apparent, and as the only objection is the aversion of the children, and no accidents ever happened to any of the children operated upon, we think it advisable to give it a fair trial.

STRICTURE OF THE ŒSOPHAGUS.

EVER since the malady of the German Crown Prince has been announced, medical writers in all parts of the civilized world, but particularly in Germany, have vied with each other in describing diseases of the upper air-passages and that region. This may have been what suggested to Dr. Renvers to review the treatment of strictures of the œsophagus by means of permanent tubes (*Arch. f. kl. Med*, 1888, xiii., H. 6). The most usual forms of stricture are hysterical or spasmodic, fibrous, and cancerous. It is with especial reference to the latter form that the treatment has been used. In view of the fact that attempts made heretofore in this direction have met with little success, and about ninety-five per cent. of such cases were incurable, it seems very discouraging to attempt any assistance. The methods usually employed have been (*a*) repeated introduction of a sound, (*b*) operative procedure from the mouth or stomach, or (*c*) nourishing by the rectum. The objections to such procedures are that a daily introduction of a sound would hasten the growth of the cancer or break through the degenerated œsophageal wall; the other methods are in many cases fatal, and, if successful, prolong the life for a very short time.

The cases reported by Symonds, Mackenzie, and others do not show the good results of this treatment. Renvers' experience is confined to five cases of stricture from carcinoma, of which the last three had been previously treated by sounds; and, in addition, they suffered from severe complications of the organs of respiration, while the first two show a more favorable history. He first used a funnel-shaped soft-rubber tube, but found that the stricture and the muscular compression exercised during swallowing narrowed the lumen, and the body-temperature soon made the rubber soft and tender. He then used hard-rubber tubes with one side smoothed, to facilitate passing it by the projecting cricoid cartilage in old subjects. When the stricture was entirely confined to the upper part of the œsophagus, near the cricoid cartilage, the soft-rubber tubes were admissible. The introduction of the tube is often very difficult. It is kept in place by silk threads tied around the ear or around a tooth. At first the difficulty of swallowing is great, and at times morphia must be given to quiet the patient after the introduction of the tube. Soft or liquid food is alone to be used, and due care must be taken in its selection. The two successful cases of Dr. Renvers were living up to the last report, and were in health, having gained in weight.

Considering the fact that such cases are generally doomed in a short time, whether operated on or not, the introduction and use of permanent œsophageal tubes opens a way for great relief in this malady. Such cases should be kept carefully under observation, and a judicious selection of tubes as to size, position, composition, should be made, in order to give this mode of treatment its best results. These experiments of Renvers seem to be simply a continuation of the work begun by Symonds (*British Medical Journal*, April 23, 1887) and others, and is a valuable addition in confirmation of what many have considered a doubtful experiment.

THE CANCER-BACILLUS, AND THE SARCOMA-BACILLUS.

Dr. Carl Francke, assistant to Professor Von Ziemssen at the Clinical Institute, at Munich, reports to the Munich Society of Morphology and Physiology that he has confirmed the discovery of Scheuerlen regarding the bacillus of cancer. He has also discovered, himself, a bacillus of sarcoma (*Münch. Med. Wochenschr.*).

Dr. Francke's experiments began last November, and he had already seen and demonstrated the bacillus of sarcoma when Scheuerlen's discovery was announced. Francke has examined nine cancers since then, and in all has observed the carcinoma-bacillus and its spores essentially as described by Scheuerlen.

His observations on the sarcoma-bacillus were based on the examination of three cases. In each instance he found a bacillus which resembled the cancer-bacillus very closely, only it was thinner and longer. The cancer-bacilli are, on the average, 2 micro-millimetres long, and 0.4 micro-millimetre broad, while the sarcoma-bacillus measures 3 to 4 by 0.4 micro-millimetres. The sarcoma spores also resemble those of carcinoma, except that they are a little larger and have a sharply contoured pole. The two organisms develop alike in culture-media, producing a reddish-brown pigment. Inoculations of the pure cultures of the sarcoma-bacillus have produced no result as yet, but Francke thinks that four weeks is too short a time for sarcoma to develop, and he will make another report later.

THE OVERWORKED BOY PIANIST.

The fact that Josef Hofmann retires from the concert stage on account of physical disability ascribed to overstrain, enhances the interest of the medical profession in the marvel. It appears that in the early part of February his work was curtailed as the result of a medical examination, and now there is a prospect of its being discontinued altogether, at least for a time.

The amount of work performed by the boy pianist since May 17th last, has been prodigious. During that period, with the exception of one month's rest, he has daily, and sometimes also nightly, performed upon the stage before large audiences, amid great excitement and corresponding nerve-strain. Playing the most difficult compositions of the great masters, improvising, and leading large orchestras, there is developed in him, as the result of this increased mental activity and emotional exaltation, a condition of nervous prostration which may in the end blight promises of a wonderful genius. The physical examination of the little musician shows that no organic disease is present, but the symptoms presented are of sufficient importance to warrant the anxious conferences of Dr. Simon Baruch, the medical attendant, with the medical gentlemen who, on behalf of the manager, have been appointed a board of examiners. It appears from these examinations that Josef is a sturdy little fellow of pronounced neurotic type. As is usual with such prodigies, he at first enjoyed the triumphs of his performances; but lately some pronounced neurotic symptoms have been noticed. Recently, his parents observed urine stains on his under-clothing and pantaloons, and the boy finally acknowledged, with much bashful reserve, that he suffered from incontinence of urine during or immediately after the performances. This aroused the usual suspicions of the lay mind, of kidney disease. Chemical and microscopical examinations of the urine developed nothing abnormal. The temperature, however, has been above the health standard, $99\frac{4}{5}$° to 100° F. in the mouth, while the pulse has ranged from 96° to 100°, and has been constantly irregular in rate, rhythm, and tension. Taking these circumstances into consideration, together with the fact that the first medical examination demonstrated the necessity for reduction in his work, it would seem that the advice of the gentleman having charge of the case—to give the little hard-worked boy complete—rest is eminently sound. With ordinary boys of his age who are overtasked at school, there would be no question as to the policy to be pursued, but with the boy pianist, whose performances are worth so much money, it appears to be an altogether different matter.

THE CAUSE OF THE COLOR OF THE SO-CALLED CALOMEL STOOLS.

It is a curious fact that, notwithstanding the frequent use that has been, and still is, made of mercurous chloride, we really know, even yet, but little positively concerning its mode of action upon the liver and the secretion of bile. The drug has generally been supposed to increase the secretion of bile, but recent experiments would seem to prove that, instead of being an hepatic stimulant, it is really a sedative, diminishing rather than increasing the secretion of bile. The peculiar color of the stools, after a dose of calomel has been taken, has been urged, as a proof of the stimulating action of the drug on the liver, as this color was assumed to be due to the presence of an excessive amount of bile in the intestinal discharges. But this explanation has also been called in question, many asserting that the color is simply an indication of an incipient ileo-colitis excited by the irritant action of the mercurial on the intestines.

The latest explanation of the color of calomel stools is given by Dr. Józef Zawadzki, of Warsaw, in a recent number of the *Pamietnik Lekarski*. As a result of a number of experiments, conducted by him in the pharmacological laboratory of Professor Tumas, the author presents the following conclusions:

1. The action of calomel is to prevent decomposition of the bile and other contents of the intestines.

2. This action does not depend upon the presence of calomel as calomel, but upon that of gray oxide of mercury, formed from mercurous chloride in the presence of an alkali.

3. The color of the stools is due to the presence of biliverdin, which passes unchanged owing to the restraining influence of the gray oxide, and which is also

formed from the bilirubin, and perhaps from the hydrobilirubin as well, through oxidation by the mercurous oxide, according to the following formula: $C_{16}H_{18}N_2O_3$ (bilirubin) + $2Hg_2O = C_{16}H_{18}N_2O_4$ (biliverdin) + $HgO + 3Hg$.

4. In those cases in which the characteristic color of the stools is not present, the cause is to be referred to a failure of this oxidation of the coloring matter of the bile through some morbid action within the intestinal canal.

Obstruction to the passage of bile, if complete, should also prevent the formation of the "calomel stools," if this explanation of the action of the mercurial be the correct one.

News of the Week.

THE NEW YORK CANCER HOSPITAL.—Since the opening of this hospital, fifty-seven patients have been admitted for treatment, and thirty-seven operations have been performed. The warming and ventilation of the building is all that could be wished. There were at one time seven cases of advanced epithelioma of the cervix in one of the circular wards, and not the slightest unpleasant odor was perceptible on entering the room. No cases, however hopeless, or however destitute of means, have been refused admission.

DR. JAMES CRAIG.—The death is announced of Dr. James Craig, of Jersey City, in the fiftieth year of his age. Dr. Craig was born in Scotland; he graduated in medicine from the New York University in 1861, and had been actively engaged in practice ever since. He was attending physician to St. Francis' Hospital.

ACUTE INFECTIOUS PHLEGMON OF THE PHARYNX is the title given by Professor Senator to a disease which he regards as a new one. That is to say, though observed by others, its clinical distinctions and pathology have not been made out. It seems, however, from the description, that the "new disease" is only another name for what has been termed erysipelas of the pharynx.

WHAT THE Germans would call a jubilee was celebrated on December 21st, by James L. Cabell, M.D., LL.D., Professor of Physiology and Surgery, in the University of Virginia. It was the anniversary of the fiftieth year of Dr. Cabell's connection with the college.

THE PATIENT WITH A CEREBRAL TUMOR, which was removed by Dr. Weir, at the New York Hospital, recovered sufficiently to go to his home in Bridgeport, Conn. We learn that he is now dead.

THE CROWN PRINCE AND ENGLISH PHYSICIANS.—One of the morning papers goes to the expense of telegraphing from London an extraordinary story, to the effect that the introduction of an English doctor into the Crown Prince's case was done in order to prevent an early operation for cancer, thereby prolonging the Crown Prince's life for a time, but making ultimate recovery impossible. Meanwhile, the Kaiser was expected to die, thus making the Crown Prince emperor and leaving his widow (an Englishwoman) a millionnaire dowager Empress, instead of a mere Princess! It is added: "Of course the implication in all this is that the English deliberately plotted the sacrifice of whatever chance of ultimate recovery the Prince had to the prospect of his becoming Emperor just long enough to leave their Princess in the possession of imperial revenues and estates and a Crown rank." We give the above as an illustration of the fantastic stories which London correspondents, who have to cable two columns of something for Sunday morning papers, can devise.

VIRCHOW'S REPORT ON THE CROWN PRINCE'S DISEASE.—The *Klinische Wochenschrift*, in an article on the condition of the Crown Prince, approves the report made by Professor Virchow, in which he says the particle coughed up by the Prince was a dead, decayed portion of the larynx which had become detached from the surface, leaving a cavity of a depth in some places of four millimetres. He found nothing to indicate a process involving gangrene. He did not see either pus-corpuscles or suppurating cells. In most places he found nothing pointing to the presence of any foreign substance. Rather a large portion of the particle coughed up was detached from an almost indurated spot, and had the form and appearance of a flat wart, in which, when cut open, a solid, whitish kernel, with a darkish, rather thick envelope was discernible to the naked eye. Within this kernel the microscope revealed clusters of epidermoidal cells, many of which had become quite homogeneous. The report draws no conclusions as to the nature of the disease.

THE FRENCH CONGRESS OF SURGERY holds its third annual session in Paris, on March 12th to 17th. The subjects to be discussed are the radical cure of hernia, the treatment of empyema, the cause of relapses after removal of tumors.

THE Fifth International Veterinary Congress will be held in Paris in September, 1889. Professor Chauveau is President of the Committee.

THE STATE HEALTH BOARD'S REPORT.—The annual report of the State Board of Health gives the total number of deaths throughout the State for 1887 as 96,453. Of this number, 35,114 deaths were of persons under five years of age. Consumption caused 11,609 deaths; diseases of the nervous system, 9,957; small-pox, 175, and typhoid fever, 1,327. The Board's report adds confirmation to the possibility of milk becoming the carrier of fever-germs, and recommends systematic supervision of sources of milk-supplies. Recommendations are made as follows: That power be given to the Superintendent of Public Instruction to enforce through Trustees the sanitary improvement of schools; that the Supreme Court, as well as county judges, be empowered to approve regulations of the Board as to the sources of water-supply for cities; more thorough organization of local health boards; relative to the quarantine station; that the health officer of the port of New York, with the State Engineer, be directed to prepare plans for such remodelling of the station as is necessary, and that these plans be submitted to the Board for approval.

LONDON MEDICAL RECORD.—The proprietorship of this journal has been changed, and it is to be continued, with its name changed to the *London Medical Recorder*.

A New Medical School has been organized at Rome, Italy, in connection with a newly founded institute, the Policlinico Umberto I. The arrangements in the new building for clinical and scientific work are on the most ample scale. The work is under the direction of Professor Bacelli.

The Laicization of the Paris Hospitals will shortly be complete. The religious staff at the Charité was dismissed a short time ago. The laicization of the Hôtel Dieu and the Hôpital St. Louis will follow in the course of the year. The laicization of the hospitals was begun in 1878, with the Hôpital Laënnec. Since that time the Administration of the Assistance Publique has organized a training-school for nurses at the Hôpital de la Pitié. The nurses are taken from there to replace the religious nurses, whenever a fresh hospital is laicized.

German Medical Congress at Wiesbaden.—The seventh annual Medical Congress will take place at Wiesbaden from April 9th to 12th, Professor Leube, of Würzburg, being the president.

Statistics of American Laparotomies.—The *Pittsburg Medical Review* gives, in tabulated form, the statistics of 422 laparotomies performed by American surgeons in the past two years. The general classification and results were: Laparotomies for removal of ovarian and parovarian tumors, 207; mortality, 13 per cent. Laparotomies for removal of ovaries not the seat of tumor, 115; mortality, 8.7 per cent. Laparotomies for other purposes than the removal of ovaries, 100; mortality, 31 per cent.

Christmas Gifts to the Crown Prince's Physicians.—It is reported that Sir Morell Mackenzie has received as a present a valuable case of instruments; Herr Krause, a diamond pin; Herr Schroeter, two superb Japanese vases; Herr Bergmann, twenty-four silver table-ornaments; and Herr Schmidt, a gold inkstand.

Doctors and Infectious Diseases.—The daily papers of the past week record this interesting item: "Dr. Edward Russell, of Brooklyn, who was arrested for concealing a case of small-pox, was fined $50 by Justice Walsh. Dr. Russell is determined to appeal the case."

The Discoverer of Chloroform.—The Chicago Medical Society, at its regular annual meeting, concurred in the unanimous report of its special committee awarding the credit of priority of discovery of chloroform to Dr. Samuel Guthrie, of America, giving references to authorities on which its conclusion is based. The report was ordered published.

Expiring Poison.—M. Brown-Sequard and Dr. Arsonval, and, independently, M. R. Wurtz, have discovered a volatile poisonous alkaloid in the expired air. This is found by Wurtz to be identical with an alkaloid circulating in the blood, and it is suggested that some of the phenomena of phthisis are due to imperfect excretion of this poison.

Chronic Nephritis with Large White Kidney may be due to an auto-toxic condition, according to M. Gaucher. The liver does not act sufficiently, and incompletely oxidized nitrogeneous products, such as leucin, tyronin, creatin, xanthin, etc., circulate in the blood and irritate the kidney. He has produced the large white kidney experimentally, by injecting these substances into animals.

California State Medical Society.—The annual meeting of the Medical Society of the State of California will be held in San Francisco, commencing April 18th.

Why Didactic Lectures?—The editor of *Gaillard's Medical Journal* refers to the letter upon the subject of didactic lectures recently published in the columns of The Medical Record, and says that, "Though the writer has carried the strain to too high a point, he has undoubtedly struck on the key-note of an error that exists to a detrimental extent in some of our diploma-giving medical colleges." He adds: "We regard the note-book as the curse of the medical student, and as the enemy of consecutive thought and memory. Instead of allowing his mind to follow the thread of the discourse, the student attempts to trace it on paper with his pencil. Let note-books be proscribed, and the medical student will take renewed interest in his didactic teacher, and find pleasure where he expects ennui." This is carrying the matter to quite as great an extreme. The note-book may be very helpful, and even indispensable, if properly used. The art of using it should be taught.

The Danger of too many Consultants.—Sir James Paget, in a lecture on "Dissection Poisons," said: "Sir William Lawrence used to say that he had not known anyone to recover on whose case more than seven had been consulted. Our art has improved. I had the happiness of being attended by ten—Sir Thomas Watson, Sir George Burrows, Sir William Jenner, Sir W. Gull, Dr. Andrew, Dr. Gee, Mr. Cæsar Hawkins, Mr. Savory, Mr. Thomas Smith, and Mr. Karkeel. In this multitude of counsellors was safety."

Hydra-naphthol and Beta-naphthol are said to be identical compounds.

Prevalence of Syphilis.—The percentage of syphilis in 620 patients, at the Berlin Poliklinik, was 11.12 per cent. In Bernhardt's clinic, at Vienna, and among private patients, 150 in all, six per cent. had syphilis. Neumann, in the Moabite Hospital, at Berlin, found among 861 male patients that 22.4 per cent. had had syphilis. Of these, 11.8 per cent. had tabes dorsalis; of the non-infected, 0.9 per cent. had tabes.

Promoting the Cause of Higher Medical Education.—An important resolution was adopted by the California Board of Medical Examiners, at its meeting on January 4, 1888. It was as follows:

"*Resolved*, That on and after April 1, 1891, the Board of Examiners of the Medical Society of the State of California will not grant certificates to practise medicine on diplomas issued after that date, by colleges which do not require that all candidates for graduation shall have studied medicine not less than three full years, and shall have attended not less than three full regular courses of lectures, delivered during three separate years."

Medical graduates will have to bear in mind the fact that they must have taken "three full regular courses of lectures" in order to be able to practise medicine in California.

Dr. Alexander W. McCoy has been elected Professor of Diseases of the Throat and Nose in the Philadelphia Polyclinic and College for Graduates in Medicine.

Pathology of Myxœdema.—Dr. Ord has contributed $500 toward the expenses of investigating the pathology of myxœdema.

The Kansas State Medical Society will hold its next annual meeting in Representative Hall, Topeka, May 1, 2, and 3, 1888.

The Illinois State Medical Society will hold its next annual meeting in Rock Island, commencing at 10 a.m., May 15, 1888.

Successful Removal of a Spinal Tumor.—A patient of Dr. Gowers was recently shown, at the London Medical and Chirurgical Society, from whom a spinal tumor had been successfully removed by a surgical operation. He had spent about three years in severe pain, which was most intense just below and inside the angle of the left scapula, and was accompanied by absolute loss of motion and sensation of the body and limbs below that level. The upper border of the anæsthesia was distinctly in the region of the fifth intercostal nerve on the left side; on the right it was less accurately defined, but did not extend higher. All the symptoms agreed with those of tumors of the spinal cord, and the intense pain afforded ample justification for making an attempt to excise the tumor. Mr. Victor Horsley accordingly removed the spines and parts of the laminæ of the fifth and fourth dorsal vertebræ; but not until the third vertebra had been similarly treated did the tumor come into sight. It was a small oval myxoma, compressing and making a deep impression on the left side of the spinal cord below the third vertebra. It was easily shelled out, and under careful antiseptic treatment the temperature did not rise more than 1° F. The wound healed rapidly, except at the uppermost point, where a drain had been left in by which a little cerebrospinal fluid flowed away very slowly. For three or four weeks the former acute pain did not lessen, and even at times seemed more agonizing; but after that it gradually and intermittently decreased, and now, after seven months, is entirely gone; the sensation and motion of the body and legs are almost completely restored. This is the first time that such an operation has been attempted.

Cheap Medical Practice in Paris.—A federation of clubs and similar societies in Paris has been formed, under the title of the "Union Médicale des Sociétés de Secours Mutuels du Département de la Seine," with the object of cheapening medical attendance. A large number of practitioners have received a circular inviting them to become members of the medical staff of the Union Médicale. Some extracts from the rules of this body are enclosed, from which it appears that the annual remuneration is fixed at 2 francs per head in the case of adults, and 1 franc, only, for children under sixteen years of age. The amount is to be paid quarterly. Medical officers must visit members as soon as possible after being sent for; they must examine candidates for admission. They must, in case of sickness or absence, find a substitute, and three months' notice must be given of retirement.

Carcinoma of the Larynx in Different Countries.—M. Mollière, of Lyons, thinks that carcinoma of the larynx must be much more common in Germany and Italy than in France and England, for while he himself, though he sees annually some seven thousand surgical patients, has never had a case suitable for extirpation of the larynx, and this operation is known to be a very uncommon one in France and in England, no less than seventy-six cases were mentioned at the Dresden Congress, and one hundred and one operations are referred to in the Italian *Archives of Laryngology*.—*Lancet.*

Reviews and Notices.

Atlas of Venereal and Skin Diseases. Edited by Prince A. Morrow, A.M., M D., Clinical Professor of Venereal Diseases, Medical Department University of New York, etc. New York: William Wood & Co. 1888.

One-eighth of the diseases afflicting man is said to be caused by venereal affections and their sequelæ, while the very large number and variety of skin diseases is well known to every practitioner of medicine. Considering, therefore, the extent and scope of the field properly embraced in the title of this work, its accomplished editor and his enterprising publishers have set for themselves no light task.

The practical demonstration of the varying characters of disease by faithful illustrative plates is a feature in scientific publications which cannot be too highly appreciated by the student and practitioner. In no departments of medicine are accurate illustrations of lesions more necessary or desirable than in those of skin and venereal diseases. No text-description, however carefully made, can equal a fine colored illustration of a chancre, a chancroid, or a mucous patch. To present these and kindred lesions in fine and realistic chromo-lithographs is high art. Each illustration carries with it a benefit which the practical man, especially the one denied of clinical opportunities, cannot too highly value.

Judging from the three numbers of this "Atlas of Venereal and Skin Diseases" which are before us, it promises to fulfil its mission as a valuable practical guide to the busy practitioner and careful student as none other has yet done.

The Atlas is issued in monthly parts, each containing five imperial-folio chromo-lithographic plates, with from fifteen to twenty pages of descriptive text of similar size. The editor, Dr. Prince A. Morrow, has succeeded in this latter in presenting in an admirable manner an intelligent epitome of the subjects of skin and venereal diseases, and of matching them with beautiful and striking flesh-tinted and life-sized illustrations of typical lesions. Associated with him in this work are Professors Kaposi and Neumann, of Vienna; Drs. Hutchinson, of London; Fournier, Hardy, Ricord, Cullerier, Besnier, and Vidal, of Paris; E. L. Keyes, F. N. Otis, and H. G. Piffard, of New York; and J. Nevins Hyde, of Chicago.

A marked feature of the publication of this Atlas is the fact that all the contributors here named, and especially Professors Kaposi and Neumann, of Vienna, are in this relation to the Atlas by their own consent, and not, as so frequently happens to foreign authors, whether they will or not. We are informed by the publishers that they have purchased from both Drs. Kaposi and Neumann the sole right to reproduce in America such of their elegant plates of skin and venereal diseases as may be desirable for Morrow's Atlas.

The three first fasciculi have been published, and are models of typographical art, while the chromo-lithographic illustrations are equal in excellence to beautifully finished water-colored drawings.

Reports of Societies.

THE PRACTITIONERS' SOCIETY OF NEW YORK.

Stated Meeting, February 3, 1888.

George F. Shrady, M.D., President, in the Chair.

Dr. Samuel Sexton referred to several cases of

FACIAL PARALYSIS

which he had seen in which the symptoms simulated disease of the ear. There was severe pain, not at the point of exit of the nerve, but at the back of the head and side of the neck. There was no tenderness along the course of the nerve. In one case, in which there was pain in the mastoid and periauricular regions, there was absolute and immediate deafness. There was no hyperakusis. In this case there was also marked hyperæsthesia of the skin.

Dr. C. L. Dana said that it was certainly very rare to encounter pain when there was affection of the facial nerve alone. He thought it not improbable that there might have been compression, from some cause, of the trifacial nerve, to which the pain could be attributed.

Dr. Beverley Robinson reported a case of

DIPHTHERIA

with the following history: Flora M——, four years of age, had been a patient in the orthopædic service in St Luke's Hospital. On November 21st the patient was noticed to have a slight cough of a croupy character. The temperature at midnight was 100° F. The following morning the fauces were seen to be markedly reddened, and several small patches were observed on the left tonsil. The case was seen by Drs. Davis and Robinson, who believed it to be one of follicular tonsillitis with, possibly, some false membrane in the larynx. On November 23d there was marked dyspnœa, with some cyanosis of the lips.

INTUBATION OF THE LARYNX

was performed by the house physician, Dr. Traub, and a marked improvement in the dyspnœa and general symptoms followed. Examination of the urine at this time showed a specific gravity of 1.024; no albumen. On the following day signs of a general bronchitis were noted, but there was no dyspnœa, and the child seemed to be very comfortable. On the next day the dyspnœa returned, and the tube was removed and found to be clogged with tenacious mucus. The temperature at this time was 104.2°. Two days later the tube was again inserted, on account of a return of the dyspnœa, and gave relief as before. The patient now became very restless, and died suddenly on the morning of November 28th, apparently from cardiac thrombosis.

At the autopsy the mucous membrane of the bronchial tubes was seen to be congested and covered by a false membrane, nearly a line in thickness in the larger tubes and apparently blocking up completely the smaller tubes. The mucous membrane of the larynx and trachea was covered by a false membrane nearly a line in thickness. The tube was still *in situ*, and where it was in contact with the tracheal and laryngeal walls the false membrane was less abundant.

Dr. Robinson called attention, especially, to the difficulty of diagnosis in the beginning and to the absence of albumen. He believed that Dr. Ball had also seen the child and had concurred in the diagnosis of follicular tonsillitis.

Dr. A. Brayton Ball said that he had seen the case, but had believed it to be diphtheria. He had now under treatment a gentleman, forty-five years of age, suffering from one of the most severe attacks of diphtheria he had ever seen.

THE UVULA WAS ENORMOUSLY SWOLLEN AND COVERED WITH MEMBRANE,

and there were also two large patches on the pharynx, but there had been none on either tonsil. The membrane was just now beginning to disappear. During the entire course of the disease there had been no fever at all. In his experience, the more the tonsils were covered the higher usually was the fever, but he was getting to doubt more and more his ability to distinguish with any degree of certainty between diphtheritic and follicular tonsillitis.

The brother of the gentleman whose case he had just related was subject to attacks of what was called follicular tonsillitis, suffering from them every winter. He had an attack this year which differed from those preceding only in the great amount of prostration accompanying it. There was high fever, but the urine was free from albumen. This patient's physician diagnosed the affection as one of follicular tonsillitis. Ten days later, however, the brother, Dr. Ball's patient, came down with the unmistakable attack of diphtheria from which he is recovering, and ten days after this his sister was attacked with what had the appearance of follicular tonsillitis. In her case, however, as in that of the first one of the family attacked, the prostration was most marked. In none of the three cases was there any albuminuria.

Dr. Ball was satisfied in his own mind that all three of these cases were true diphtheria, although two of them presented the appearances rather of follicular tonsillitis. He believed that the second brother caught the disease from the first, and the sister, probably, from him.

Dr. Robinson said that, in this country, physicians recognized usually only diphtheria and follicular tonsillitis, though Da Costa has described a form of "membranous sore throat" differing from either. Rilliet and Barthez, however, speak of a distinct affection of a benign character which they call

HERPETIC SORE THROAT,

or membranous angina. He would ask Dr. Ball if he had ever seen any cases of this nature.

Dr. Ball replied that he had never recognized such an affection. He was certain, however, that the case related by him was not of this nature, but was one of genuine diphtheria.

Dr. William T. Bull then read a paper (see p. 205) entitled

REPORT OF CASES OF INTESTINAL OBSTRUCTION TREATED BY LAPAROTOMY.

Dr. G. L. Peabody agreed with the author of the paper that operation should be resorted to after medical treatment has proved ineffectual, but he thought the limit of twenty-four, or even of forty-eight, hours was too narrow. He had now a patient who was convalescent, who had been without a passage from the bowels for ten days and was supposed to be suffering from strangulation. The obstruction had, however, yielded to medical treatment. It was impossible to lay down any definite period for waiting before a resort to surgical measures, but certainly the latter should not be undertaken until after persistent efforts to relieve the obstruction had been made and failed.

Dr. Polk thought the general condition of the patient should be relied upon to determine the proper time for operating. When symptoms of distress supervene and it becomes evident that the patient's vitality is being reduced, then delay is no longer admissible. He reported two cases in which he had operated. The first patient was a woman, fifty-five years of age, who had had some symptoms of obstruction for about three months. It was thought that the obstruction was in the sigmoid flexure. A small tumor, about the size of a hickory-nut, could be felt to the left of the uterus, resembling a cystic ovary except that it was too movable. An incision was made in the median line, and the point of constriction was picked up and drawn out within two minutes. The intestine was greatly distended and the mesorectum was found to be in a cancerous condition, so resection was not performed, but the intestine was stitched to the abdominal wall and, as the patient lived in the country and could not be seen again, it was opened at once. The patient has made a good recovery. The speaker was struck with the advantage of making the

OPENING IN THE MEDIAN LINE.

The second case was that of a young woman who had presented symptoms of intestinal obstruction, which it was thought could be overcome by means of cathartics, but the attempt to do so failed. After incision it was found that rupture of the intestine had occurred. The patient died two weeks later. She gave a history of old pelvic inflammation.

Dr. Weir agreed with Dr. Bull that these operations were often made too late. He would not go so far as to say that every case of intestinal obstruction was a surgical one, but he thought that a surgeon and physician should watch the case together from the commencement. A great deal of time was often lost in getting the surgeon thoroughly acquainted with the case, when he was not called in until the last moment. He had had seven cases, three of lumbar colotomy and four of laparotomy. In three of the laparotomy cases the obstruction was caused by bands. In one case there were two constricting bands, the second of which was discovered only at the autopsy.

He thought the length of time consumed in laparotomy was a very important consideration. The reader of the paper had spoken of the great amount of shock following eventration, but he had seen considerable shock caused by the introduction of the hand into the abdominal cavity and the search for the point of obstruction, even when the intestines were not taken outside. He did not believe in the heroic incision, along the entire length of the abdomen, which had been proposed by one operator, but he thought that a tolerably long incision was best, especially when the intestine was greatly distended, in order to facilitate the search for the obstruction and shorten the operation. It was not always feasible to make an artificial anus in the median line, especially when the obstruction was found in the ascending or descending colon. As a substitute for the artificial anus, with its discomforts, Dr. Senn had proposed establishing what he called an

INTESTINAL ANASTOMOSIS,

by making a communication between the portions of bowel above and below the seat of obstruction. He used two plates of decalcified bone, which were inserted into the lumen of the two portions of intestine and united by sutures, thus bringing two broad surfaces of peritoneum in apposition and securing firm union.

Dr. Robinson was in favor of exhausting medical means, as long as the patient's condition seemed to warrant it, before resorting to operation. He thought that better effects were often to be obtained from frequent doses of laxatives than from powerful purgatives. It was not always an easy matter to decide whether fecal matter had passed the point of obstruction or whether what appeared in response to enemata was simply part of the accumulation in the portion of bowel below the seat of obstruction. In order to decide this point, a dose of calomel might be of the greatest service by reason of the color which it imparted to the stools.

Dr. Harrison had found calomel very useful in one case. If it was once established with certainty that total obstruction existed, he thought further delay was useless.

Dr. J. B. Hunter thought that by far the most difficult point to decide was when, and when not, to interfere. He recalled one case in which the hour for operation had been determined upon and everything was in readiness, but the obstruction yielded, the temperature went down, and the patient recovered without operation. In a certain number of cases the operation fails to give relief even when the stricture is found, as when extensive adhesions are present. He did not regard it as always a safe thing to give calomel when obstruction existed, for he had seen a case of extreme salivation from five grains of this drug.

Dr. B. F. Curtis had been surprised to find, in looking over the literature of the subject, how often surgeons had operated upon patients in a state of extreme collapse. The worse the condition of the patient the longer should be the abdominal incision, for in such cases saving of time in operating was of extreme importance.

Dr. Draper recalled a case, which had also been seen by Dr. Weir, occurring some years ago, in which the knowledge now possessed of intestinal obstruction would doubtless have been of great assistance. The patient had pain, nausea, and vomiting, but for a week there was no distention of the bowels nor any symptom of peritonitis. The patient died on the eighth or ninth day of his sickness, and at the autopsy a large gall-stone was found which had ulcerated from the common duct into the duodenum and had then passed down nearly to the cæcum. The case would have been a very favorable one for laparotomy. When the obstruction exists in the small intestine, he would advise early operative interference, but when it is in the large intestine, and there is much tympanites, he would delay operation. Many of the latter cases would be found to yield to the opium-treatment.

Dr. Weir remarked that this case showed well the advances which surgery had made. It might not have been necessary to open the intestine, even had laparotomy been performed, for the stone might possibly have been crushed with padded forceps, broken up with a needle, or pushed along into the large bowel.

Dr. Loring recalled a case which he had seen a number of years ago, in which no passage from the bowels took place for five days, and there was great doubt whether obstruction existed or not. The symptoms finally subsided, and the patient recovered. Opium had been used freely in this case, and he would like to ask Dr. Bull whether at the present time, in view of a possible operation, he would give the drug so liberally.

Dr. Bull replied that he would give opium in sufficient quantity to quiet the pain, if possible, but not so as to narcotize the patient. He was learning to avoid the use of morphine, as far as was compatible with the comfort of the patient, in abdominal complaints. He did not insist upon a limit of twenty-four or forty-eight hours as an inflexible rule in every case, but wished that statement to be taken in a very general sense. Persistence of the pain and vomiting and failure to obtain a movement of the bowels were the indications for operation. It might possibly happen that a case now and then would have recovered without surgical interference, but he believed that such a plan would be for the best interests of the greatest number of patients. What was now needed was a greater refinement in diagnosis. The main point of the existence of obstruction seemed to him to be comparatively easy to determine, but the question of the locality or of the nature of the obstruction was one that was often very difficult to decide.

The Society then adjourned.

Professional Devotion.—Dr. Eustace, of Alresford, England, is to be congratulated upon the successful result of a heroic operation. A short time since this gentleman was summoned at night to the bedside of a patient who was sinking from the effects of previous uterine hemorrhage. After an unsuccessful attempt at direct transfusion from his own arm, he drew off six ounces into a basin and injected it with a syringe, with the result that the patient ultimately recovered.—*Med. Press.*

MEDICO-CHIRURGICAL SOCIETY OF GERMAN PHYSICIANS OF NEW YORK.

Stated Meeting, February 6, 1888.

L. Weber, M.D., President, in the Chair.

Dr. M. Einhorn gave a

PRACTICAL DEMONSTRATION OF THE MOST RECENT TESTS FOR HYDROCHLORIC ACID IN THE CONTENTS OF THE STOMACH.

He said that the importance, especially in chronic diseases of the stomach, of ascertaining the chemical function of the affected organ, must be evident to all. As was well known, the chemical function of the stomach consisted in that it responded to stimulation (which was physiologically produced by the ingestion of food) by the secretion of a fluid, the principal ingredients of which were hydróchloric acid and pepsin. By means of these the gastric juice was enabled to digest albumen.

But while pepsin exerted its action though present in very small quantities (according to Petit one part of pepsin dissolves in seven hours five hundred thousand times its weight of fibrin), and was harmless even when present in larger amounts, the same could not be said of hydrochloric acid. Thus, in the proportion of 1 pro mille, hydrochloric acid interfered with digestion, and in quantities of 3 pro mille and over it became positively injurious to the stomach-walls.

Therefore it was always important in gastric derangements to discover whether hydrochloric acid was present at all, and if so, whether normally, less than normally, or excessively present.

For the examination of hydrochloric acid we proceeded as follows:

The stomach contents, obtained in the usual way by means of a tube, were filtered. The reaction of the fluid was then determined by means of litmus-paper. If acid, the question arose whether this reaction was due to acid salts or to free acids. For the determination of this point a few drops of the fluid to be examined were poured into a test-tube containing a small quantity (1 to 2 c.c., *i.e.*, fifteen to thirty grains) of a saturated alcoholic tropæcolin solution. Free acids produced a deep, dark, brown-red color, the presence of acid salts a yellowish tint.

To decide whether the obtained acid was of an organic or inorganic nature (*i.e.*, hydrochloric acid), the following reactions had been, until lately, generally in use:

Weak alcoholic solutions of about 0.2 per cent. methylviolet, Congo red, fuchsin.

The changes arising from these anilin-colors with hydrochloric acid were:

1. Methylviolet + HCl = blue.
2. Congo red + HCl = dark blue.
3. Fuchsin + HCl = yellowish, colorless.

Besides these, there were two other well-known reactions. One was Uffelmann's test, an alcoholic extract of bilberries giving, with hydrochloric acid, a red color. The second was Rheoch's test. The reagent fluid consisted of:

Sol. kal. rhodan. (ten per cent.)	2.0
Liq. ferri acet. neutr	0.5
Aq. dest	q. s. ad 10.0

A few drops of this mixture are poured upon a white plate, and one to two drops of the fluid to be examined are brought in contact with them. The presence of hydrochloric acid changes, after a few seconds, the yellowish color of the mixture into a dark-red one.

Of these various tests the reactions produced by methylviolet and Congo red were the most reliable.

Nevertheless, all the above-mentioned tests, including that of Uffelmann and Rheoch, possessed the disadvantage of giving the same reaction with concentrated organic acids. Moreover, the delicacy of these tests was lessened by the presence of peptones. For these reasons, in order to obtain a positive knowledge of the presence of hydrochloric acid by those tests, it was necessary to determine the degree of acidity of the fluid to be examined, and also to be sure that no organic acid, of similar concentration, could have produced the color-changes mentioned.

Therefore the finding of a reaction for hydrochloric acid which was not also produced by the most concentrated organic acids, and the delicacy of which was not lessened by the presence of peptones, must be regarded as a decided step in advance. The phloroglucin-vanillin test answered to those requirements. It had been used in chemistry by Singer and Etti, and during the last year it had been introduced into medicine by Guenzburg.[1] This test is performed as follows: A few drops of the following solution—two parts phloroglucin, one part vanillin, and thirty parts alcohol—instantly produce, with concentrated hydrochloric [2] acid, an intensely red color. In the presence of dilute hydrochloric acid a red color arises after warming slightly a few drops (two or three) of the fluid to be tested with about the same quantity of the reagent. A small white porcelain plate and an alcohol lamp are used for this purpose. During the evaporation of the fluid, cherry-red crystals are formed. Even $\frac{1}{20}$ pro mille of hydrochloric acid will produce a red zone at the edge of the fluid, when employing this test.

Lately the speaker had been using Guenzburg's test exclusively, because of its accuracy and extreme delicacy.

The speaker here demonstrated successfully the above hydrochloric acid tests, as well as the phloroglucin-vanillin test, employing a fluid which he had obtained that morning from the stomach of a patient suffering from gastric hypersecretion. He also showed that a twenty per cent. solution of lactic acid—*i.e.*, the acid which occurs in the stomach oftener than any other organic acid—does not give the slightest reaction with Guenzburg's test.

The phloroglucin-vanillin test was very easily performed, and was, in addition, the surest and most sensitive. Consequently it should be preferred to all other tests, and could be recommended without any further consideration.

As regards the quantitative determination of the acidity of the stomach contents, this was of great value for determining the choice of therapeutic measures to be instituted. During the past few months von Sohlern [3] had showed that in most stomach diseases, with too much or too little hydrochloric acid, the normal proportion became re-established after a course of treatment lasting from three to six weeks.

According to von Sohlern the normal quantity of hydrochloric acid occurring three hours after a meal consisting of one plate of bouillon, rice, and beefsteak, equalled 0.22 to 0.28 per cent.

Clinically it was sufficient to determine the degree of acidity in the stomach contents, and to reckon this as hydrochloric acid, provided, of course, that the presence of this acid had been qualitatively proven.

The speaker then continued: "The degree of acidity is determined in the following way: 5 c.c. (about seventy minims) of the filtered stomach contents are poured into a small glass; then a few drops (one to three) of litmus tincture or of a one per cent. alcoholic solution of phenolphthalein are added; next we add of one-tenth normal sodium hydrate solution as much as is sufficient to make the fluid slightly blue when litmus, or red when phenolphthalein, has been taken as indicator. The quantity of the sodium hydrate solution used affords us the means of finding the degree of acidity (1 c.c. normal sodium hydrate solution = 0.036 grm. HCl). To compute the degree of acidity in decimals, multiply the number of the c.c. (one-tenth sodium hydrate solution) used by 100 × 0.00365, *i.e.* by 0.365; then divide by the number of c.c. taken from the fluid to be examined.

---

[1] Centralblatt f. klin. Med., 1887, No. 40.

[2] The same is the case with other inorganic acids, but as we know that in the stomach only one inorganic acid is formed (namely, the hydrochloric), we speak only of this.

[3] Berlin. klin. Wochenschr., 1887, No. 50.

"In connection with this demonstration I take the liberty of exhibiting to you two patients with a diametrically opposed condition of the stomach in reference to hydrochloric acid. One of these patients suffers from hypersecretion associated with hyperacidity of the gastric juice, the other shows a complete absence of hydrochloric acid in his gastric juice.

"I must ask your indulgence for a clinical history of these two cases until the next meeting; but to-night let me show you the condition of the hydrochloric acid in these two patients. I have made the following experiment: At 7.30 o'clock this evening I have emptied and washed the stomachs of both patients, and at 7.45 each of them ate the whites of two eggs and drank 100 c.c. of water. It is now 8.45 o'clock, and I shall take a specimen of fluid from their stomachs by Ewald's method, in order to demonstrate to you the marked difference."

The speaker demonstrated this on his patients, the stomach contents of both still showing small particles of the white of egg. One specimen gave all the hydrochloric acid reactions; the other was weakly acid from the presence of acid salts, but did not show the slightest reaction for free acids.

Dr. F. Kammerer then gave a demonstration of

GIRDNER'S TELEPHONIC APPARATUS FOR THE LOCATION OF BULLETS.

A paper was read by Dr. E. Fridenberg on the

SURGICAL OPENING OF THE MASTOID PROCESS,

in which early surgical interference was strongly advocated, provided always that an accurate diagnosis had been made.

The President related a case of bilateral mastoid disease, in which speedy recovery had followed opening and drainage of the mastoid cells. He also emphasized the importance of chiselling in as flat a way as possible, *i.e.*, never lifting the instrument perpendicularly. He said further that due care should be had not to make the preliminary incision too small. The bone-drill he discarded altogether as unscientific and dangerous.

Dr. B. Scharlau then made some remarks on

THE UTILITY OF THE LATERAL DECUBITUS IN OBSTETRICS.

He said that, so far as he was aware, the principles on which the employment of the lateral decubitus for the correction of certain fœtal malpositions were based had been first clearly enunciated by Dr. Martin, of Berlin, the father of the well-known gynecologist of that city. For the past twenty-four years he had practised, and had induced others to practise, in accordance with these principles. It was a matter of surprise to him that the current text-books of obstetrics had little or nothing to say on this subject. The leading idea was to utilize the force of gravity. The woman was to be placed on her side, so as to permit the weight of the fundus uteri to incline the upper portion of the uterus in one direction, while the lower end would thus be moved in the opposite direction.

In practice it was found that the fœtus most frequently lay in the first position, *i.e.*, the left occipito-anterior one. Now, if labor was retarded owing to failure of the head to properly engage, the woman should be placed on her left side. It would then be found that the maternal decubitus would favorably influence the position of the child in utero. The head would engage, and delivery was often speedily accomplished without instrumental aid.

Again, if the fœtal head manifested a tendency to slip away toward the right side, above the brim of the pelvis, the parous woman should be placed in the right lateral decubitus, and the weight of the fundus would divert the head in the opposite direction.

In face presentations the same plan of treatment was to be followed, only here the position of the woman was to be the opposite of that mentioned as applicable to vertex presentations.

For transverse presentations no aid could be had from changing the decubitus of the mother. In applying the forceps the lateral decubitus was likewise of no use. The operation of turning could often be greatly facilitated, however, by placing the woman on her side.

Dr. Kucher said that labor was frequently delayed in transverse presentations in consequence of the accoucheur introducing his hand on the wrong side of the infant. He was not only ready to admit the advantage to be derived from a proper decubitus of the mother, but had himself often employed this means of hastening tedious labors.

Dr. Krug stated that the principles laid down by Dr. Scharlau had no novelty for him. At the lying-in institute of the University of Freiburg he had become thoroughly familiar with their application, and he believed they were well known and appreciated in Germany.

Correspondence.

OUR PARIS LETTER.

(From our Special Correspondent.)

"CONTAGIOUSNESS OF MURDER"—THE PERIODICITY OF SPECIAL CRIMES—THE INFLUENCES OF HEREDITY AND EXAMPLE.

Paris, February 3, 1888.

The astonishing facility with which crimes are being committed in this country, the almost absolute similitude in the means of their execution, the apparent periodical return of certain forms of murder, induced Dr. Aubry to make researches as to the cause, and what the mysterious link was that connected these different states. The author consigned the results to his thesis for the doctorate, the title of which is, "Contagiousness of Murder." The term contagiousness would in this case appear to be a misnomer, as it would convey the idea of the transmissibility of a morbid psychological condition occurring after the manner of corporeal affections, which are known to be infectious or contagious; but as there is no other term in English or French, or perhaps in any other language by which the proper idea may be expressed, we must only accept the term as it is at present employed in medical literature. The morbid psychological phenomenon in question is, according to the author, not the result of a simple imitation, as one would be led to believe, but it consists of a combination of four very distinct conditions, viz.: suggestion, imitation, heredity, and contagiousness, which, together, constitute the principal elements of an epidemic. In other words, no person can undergo the influence of the contagion of a crime unless he possesses a morbid receptivity—that is to say, a soil previously prepared for the germination of the seed. It is thus that, in a room of hysterics or epileptics, an isolated attack is soon followed by other attacks among those present. In general massacres, the sight of blood excites the furor of the populace, who then blindly commit the greatest crimes. It is equally after this manner that may be explained the epidemics of St. Vitus' dance, of tarantism, and other convulsions; the strangest accounts of which have been transmitted in history. The epidemics of murder have been clearly demonstrated in history, but it is only within the last few years that the veritably pathological nature of these epidemics has been understood. Encouraged by the example of his masters, Dr. Aubry has treated the question with the authority of the experience he had acquired in the special asylums of Paris. His work is divided into three parts. In the first he studied the contagiousness of murder in its general forms, he examined what were the great factors, and in this connection passed in review the family, the prison, the spectacle of executions, and the reading of works which excite a morbid propensity. In the second part the author treats of the contagiousness of crime in its special forms: vitriol, revolver, poisoning, incineration, and the criminal cutting up into pieces of bodies. In the third part, epidemics and endemics are considered. The idea of murder, continues the author, is essentially contagious. For it to manifest itself two factors are necessary: 1, Heredity or its degeneration; 2, education, and under this head Dr. Aubry comprehends the action of example. The relation of a crime, reproduced with minute details by the public press, leads almost always to a series of crimes, the means of the execution of which are, so to say, copied on the same "crime-type." Acts of cruelty which are witnessed during great political and social commotions are known to be the result of the great masses being drawn into them by a few excited individuals. There is, in fact, in this case, a veritable imitative contagion. Heredity, the implacable laws of which appear to influence every living being, plays an immense rôle in criminality. It exists in beings morally degraded, as it exists in those who are physically degenerated. There are families of murderers, as there exist families of musicians. The author, however, does not wish it to be understood that he would deny the influence of a sound education to remedy or prevent this hereditary propensity to crime. It may, however, be remarked that while criminality has diminished in this country, insanity, in its various forms, has quadruply increased during the last half century. The *crimes célèbres*, as well as striking events, are capable of dangerously deranging the brains of those who are already predisposed to such influences, whereas the same events would have no effect on a sound mind. Science is daily discovering new forms and unexpected causes of insanity. Very recently Dr. Charpentier, of the Bicétre Asylum, attributed an attack of mania to the existence of hæmorrhoids; Dr. Lannois had met with cases of insanity caused by affections of the ear. Dr. Bataille wrote a very remarkable thesis, in which he endeavored to demonstrate the part played by traumatism as an exciting cause of neuroses. But heredity seems always to be the primordial condition, "the cause of causes of insanity," as expressed by Moreau de Tours. Without the degeneration induced by morbid heredity, the other causes of insanity are, so to say, powerless. In seeking for heredity in criminals, and in thus calculating the possible relation between crime and neurosis Lombroso, and other authors have arrived at the conclusion that crime is often a malady. The limit, however, between crime and insanity are frequently very ill defined. Take, for instance, the three delinquents that created so much sensation lately in Paris: A man who murdered his wife and two children; Aubertin, who attempted the life of M. Jules Ferry; and the third, who murdered another man through jealousy, all three are still under observation. The first is an "alcoholic," the second is a general paralytic, and the third is affected with the "delirium of persecution." But the insanity of criminals is not always so well marked as in the three preceding cases. Whatever may be the cause, there is no doubt that, notwithstanding the assertion of Dr. Aubry to the contrary, crime, and particularly murder, is more rife now than it has ever been in this country; for scarcely a day passes without one hearing of a murder being committed in Paris. For this state of things Dr. Moreau de Tours proposes the following preventive measures: 1, A healthy, moral, individual hygiene; 2, the moralization of habits; 3, a restriction on the press for the publication of crimes; 4, a more logical severity in the judgment of tribunals.

OUR LONDON LETTER.

(From our Special Correspondent.)

THE STRUGGLE AT THE COLLEGE OF SURGEONS—NOTES AT THE SOCIETIES—TUBERCULAR DISEASE OF THE TESTIS—SHALL WE INJECT A RUPTURED BLADDER AFTER SUTURING THE RENT?—IDIOPATHIC DILATATION OF THE COLON—GANGRENE FROM EMBOLISM IN HEART DISEASE—HEART DISEASE FOR HALF A CENTURY—THE PROGNOSIS OF NEURO-RETINITIS IN BRIGHT'S DISEASE—THE TEACHING UNIVERSITY FOR LONDON—THE COMITIA AT THE COLLEGE OF PHYSICIANS.

LONDON, February 4, 1888.

THE struggle at the College of Surgeons still continues. It has now entered upon another phase, the Council having, for the first time in the controversy, condescended to defend their position by argument. This is, at any rate, what they attempt to do in the statement they have just forwarded to the Lord President of the Privy Council. They still persist in the fallacy—repeatedly exposed—of assuming that they have eighteen thousand members. This is no doubt done with a view to minimize the importance of the petition to the Privy Council, signed by nearly five thousand members. The Association of Members held their annual meeting a few days since, followed by the first annual dinner. The Association is pledged to continued action on behalf of the members. Some extraordinary instances of the tactics of the Council in the past were narrated at the dinner by one of the speakers, who, although a Fellow, is evidently in full sympathy with the cause of the Members.

At the last meeting of the Medical and Chirurgical Society, Mr. W. H. Bennett, of St. George's Hospital, read a paper on tubercular disease of the testis. Five cases were described which had been specially selected because they all had an absolutely perfect family history, and also all but one (who had had syphilis twenty-three years previously) could show a perfectly clean bill of health up to the time of onset of the disease. In every one the disease was traceable to direct local irritation—traumatic in four, gonorrhœal in one. In each case the spinal column showed evidence of disease before the opposite testis became involved. In none of the cases did the affection manifest itself in other parts until after the original disease had broken down. He concluded that the rational treatment of such cases is castration upon the appearance of symptoms of disintegration about the original disease. Mr. Howard Marsh disagreed with Mr. Bennett as to the tendency of local tubercular disease to become generalized, which he thought rare. Mr. Clutton observed that in hospital out-patient practice, patients usually had both testes involved before we saw them. Mr. Bruce Clark remarked that it was easy to understand how tubercular disease of the testis spread so much more readily than that of a joint, for a colored material, such as Berlin blue, if injected into the testis, spread upward easily into the thoracic duct.

Mr. Walsham then read a case of intraperitoneal rupture of the bladder for which abdominal section was performed, and the bladder successfully sutured. The paper was followed by a short discussion, turning mainly on the desirability, or otherwise, of injecting the bladder after putting in the sutures. Mr. Holmes thought there was a danger of tearing out the sutures, but most of the speakers thought it a good plan to prove the bladder to be water-tight.

At the Clinical Society a paper (of which Dr. Money and Mr. Stephen Paget were joint authors) was read on idiopathic dilatation of the colon. The patient was an habitual drunkard, aged fifty-five, who suffered from dyspnœa and bronchitis. The colon was enormously distended. The girth of the patient was over five feet, and the measure from the ensiform cartilage to the pubes twenty-six inches. Repeated punctures gave much relief—so much so that he discontinued treatment and returned to his drunken habits. A week later he was admitted into University College Hospital, under Dr. Money. He was suffering from dyspnœa, lividity, and the same distention was present. The long rectal tube was used, and gave great relief, but he died in a week. At the necropsy all the signs of habitual drunkenness were found, including typical hobnail liver. There was enormous distention of the colon, principally of the sigmoid flexure, which formed two huge sacs, extending across the abdominal cavity. There was no organic stricture, but Dr. Money thought that the sigmoid flexure might have been twisted, or that spasmodic stricture might have been present. The bowel was hypertrophied as well as dilated. Dr. Hadden narrated two cases of sigmoid distention, and Sir Dyce Duckworth mentioned a case of enormous dilatation of the cæcum. Dr. Broadbent referred to congenital elongation of the sigmoid flexure as a cause of hypertrophy and dilatation of the colon, and mentioned a case of enormous dilatation of the colon, with chronic constipation, which was successfully treated by the administration of enemata to the patient—the latter resting on his elbows and knees.

Dr. Burney Yeo related a case in which embolism of the right axillary artery occurred in a patient suffering from mitral stenosis. Gangrene of the forearm ensued, and amputation through the middle of the arm was performed by Sir Joseph Lister. Embolic pleuro-pneumonia, however, occurred, and the patient died. Dr. Broadbent observed that it was, in his experience, rare for emboli to cause gangrene of a limb in cases of heart disease. Mr. Bowlby mentioned two cases of gangrene following embolism from heart disease in patients advanced in life. Dr. Drewitt mentioned a case of embolism of the common iliac artery, occurring in a girl, aged thirteen, during typhoid fever. Gangrene of the left leg followed, for which amputation was successfully performed.

The most interesting paper of the evening was one read by Dr. Kingston Fowler, which described the case of a patient who had suffered from heart disease for fifty-four years. In 1834 the patient, then a boy, aged thirteen, was admitted into Middlesex Hospital under the late Sir Thomas Watson (then Dr. Thomas Watson), for acute rheumatism, for which he was under treatment for nine months. There was no written record of the early history, but there was good circumstantial evidence that the cardiac lesions now present occurred during the attack of acute rheumatism in 1834. The patient remembered leeches and blisters having been applied to his chest repeatedly; also that gentlemen who had auscultated him had spoken of blowing and whistling sounds. Dr. Watson had told the patient's mother that he was never to leave home without telling her where he was going, and he had, consequently, for three years always carried with him a card with his name and address upon it. No return of the rheumatic affection had ever occurred, and the patient had scarcely been absent from work for a single day during the last fifty-four years. He was a remarkable example of a stationary lesion of rheumatic origin, in which compensation had occurred and remained perfect. The signs now present were: Systolic recession of the epigastrium; apex-beat forcible, and felt in fifth space in nipple-line; at apex, first sound accompanied by a systolic murmur; at base, in the aortic area, a short systolic bruit and a rough diastolic murmur replacing the second sound. Pulse small and collapsing. Urine free from albumen.

At the Ophthalmological Society, on January 26th, among the papers read was one by Dr. Miles Miley on the prognosis of neuro-retinitis in Bright's disease. The paper was mainly statistical, and was based upon the examination of the records of three hundred and seventy-five cases in the "London Hospital Medical Register." From his inquiries the author concluded that the retinal changes occur late in renal disease; that their presence renders the prognosis much worse, the mortality among the affected cases being doubled; that the prognosis was so bad that not one had lived eighteen months after the changes had been noted; and that the ophthalmoscope, therefore, afforded a most valuable index as to the course any given case of Bright's disease was taking, except, perhaps, in pregnancy cases. Mr. Simeon Snell read a paper on the same subject, in which he also referred to the better prognosis of retinitis associated with pregnancy. Mr. McHardy mentioned the case of a hospital patient who had lived two years after the discovery of retinitis. Dr. Van Milligen referred to a case in which the patient (still living) had had retinitis of one eye for eight years.

The proposed Teaching University for London does not make much headway. The chief work done as yet by its promoters has apparently been to evoke the opposition of all other bodies. It is unfortunate that the two medical colleges cannot see their way to act in harmony with the promoters of the Teaching University. Both would thereby benefit. As it is, it is extremely doubtful whether the Government will confer the right to grant degrees in medicine and surgery on two exclusively professional corporations, one of which is at open war with its own Fellows and Members.

No decision was arrived at at the Comitia of the College of Physicians, held last week, to consider the question of Fellows and Members of the College contributing articles to, or allowing themselves to be advertised in, journals professing to supply medical knowledge to the public. The Senior Censor moved a resolution declaring it undesirable. It is an open secret that the two journals aimed at are *The Hospital* and *Baby*. One of the Fellows wished to render the resolution still more stringent. Great difference of opinion prevailed, and, as might have been anticipated, the discussion was adjourned.

DILATATION OF THE STOMACH.

To the Editor of The Medical Record.

Sir: *A propos* to the valuable paper of Dr. Smith[1] on dilatation of the stomach, I desire in this note to direct attention to certain measures for the relief of those cases which the author has omitted to mention, or has, in my opinion, passed over too lightly.

a. It will be conceded that nutrition and the alleviation of hunger are two of the most prominent indications in the management of any severe case, and that the stomach cannot be relied upon in attaining these ends. The only other available avenue for the introduction of nutriment into the system is the rectum, and my experience in a considerable number of cases has convinced me that recourse may be had to nourishing rectal injections with a great deal of confidence. The particular injection which I recommend has for its basis a half-pint of milk and the yolks of two eggs. To this may be added pancreatine or other digestive, brandy or other alcoholic stimulant, and any medicinal agents which are indicated.[2] By exercising great care in the technique of the operation, and temporarily suspending them upon the approach of rectal intolerance, such enemata may be given six or eight times in the twenty-four hours, and continued for months.

In the vast majority of instances of pronounced and persistent gastroectasis the condition is due to incurable causes, and in these relief only can be afforded, and this is done more fully by these injections than by any other method. Now and then, however, cases present themselves which do not belong to this list, and that are susceptible not simply of amelioration but of a cure, and in these we have in rectal injections the only rational treatment, in that the stomach obtains rest, during which its muscular walls are regaining lost tone and resiliency.

---

[1] See The Medical Record, p. 120, current volume.

[2] The addition of coffee, as by boiling a tablespoonful of the ground and roasted bean with the milk for half an hour, is useful in counteracting the mental depression attending many of these cases.

β. The diet should be liquid, non-coagulable, and as sparing as possible.[1] Hunger and thirst, in some cases not fully satisfied by the enemata, is in some instances so imperative that it must be satisfied, and the indications are to use only such food as causes the minimum of discomfort.

γ. For some time after food is taken into the stomach the patient should assume the recumbent position upon the right side, and with the pelvis and lower portion of the abdomen elevated, in order to favor the exit of the gastric contents through the pylorus.

δ. In the way of medicine I have seen positive and direct benefit derived only from the administration of small doses of saline laxatives.

Edward F. Wells, M.D.

Chicago, Ill.

CONCERNING SPECIFICS IN DIPHTHERIA.

To the Editor of The Medical Record.

Sir: Under the caption of "Sure Cures and Specifics," one of your correspondents writes, in your issue of February 11th, a criticism of my "Therapeutic Memoranda on Diphtheria," to which I desire to reply.

The Record is fortunate in being the organ by which the noble indignation of so sensitive a nature seeks expression.

Your correspondent's superfine ethical sense is offended by "the general practice of publishing" cures "for so many human ailments;" but the "frequent announcement that a remedy for this mortal malady (diphtheria) has been found" arouses his holy horror.

It does not seem to occur to your correspondent that he plays sad havoc with the Queen's English when he hurls his anathemas indiscriminately against "remedies, cures, and specifics," nor does the idea seem to occur to him that other physicians may not (as he does) regard diphtheria as a "mortal malady" to the extent that they must not, on pain of being classed with "ignorant quacks, in or out of the profession," dare to suggest a "remedy."

In this sordid age it is refreshing to meet so lofty an exemplar of professional morals, and it would perhaps be "good policy" to allow his homily to pass unchallenged. But, since he has taken my essay as a text, I desire to call the attention of your readers to the *fact*, that in my "Memoranda" there is not one word said of "sure cures or specifics." On the contrary, my statements are made as cautiously as a subject of empirical knowledge admits.

I said: "If there be any therapeutic method, any combination of remedies by which its duration can be shortened or its type modified, we are obligated to adopt it."

Again: "By a process of selection I have reached a mode of treatment which I desire to submit to your consideration, because it has enabled me to cope successfully with many desperate cases."

Turpentine, so far from being lauded as a "sure cure or specific," is referred to in the following terms: "In oil of turpentine we have a more recent remedy, which during the brief time of its clinical history has been so thoroughly tested in private as well as hospital practice, that I must urge upon you its claim as a valuable agent in modifying and shortening the disease."

"It is needless to say, however, that I shall continue to strive for improvement," etc.

It must, indeed, be a singular mental organization which would distort these cautious statements into a belief in a "specific cure or antidote," or in a "reasonably *sure* cure for diphtheria" even. Your correspondent says that in his two fatal cases, in which he "found patches of diphtheritic membrane in (that novel location) the stools, turpentine was given, though in smaller doses than those recommended by Dr. B." I distinctly emphasized the importance of administering large doses of turpentine, and entered into even tedious detail to show that, while small doses of turpentine are useless and may damage the kidneys, large doses afford immunity from this danger. If this critic would permit his fine ethical sense to remain somewhat in abeyance, and afford the empirical sense to come to the front, he may yet learn from more careful reading and adoption of therapeutical measures, recommended and fortified by hospital statistics, something useful to those of his patients who are stricken by *mortal maladies*.

But he would have "the medical profession tell the community the truth" about diphtheria, which would be, according to his view, that it is a *mortal malady*. As he "condemns the too frequent announcement that a *remedy* for this mortal malady has been found," the logical deduction would be that in these cases (diphtheria) he would simply make the diagnosis and abandon the patient to his fate.

As "the medical profession" continues "to write and talk so much about cures," our critic trembles for "the good name and respect which it should enjoy in the public estimation." Is it surprising that the mind which classifies remedies, cures, and specifics together, fails to discern the difference between "the statements of the regular physician" and the "record of the most ignorant quack," and lacks the penetration to distinguish between publications made in the medical press and those in the secular journals? Respectfully,

Simon Baruch, M.D.

47 East Sixtieth Street, February 15, 1888.

THE OPERATION FOR LACERATED PERINEUM.

To the Editor of The Medical Record.

Sir: Your correspondent from St. Louis, in a recent issue of The Medical Record, asks you to inform him whether Lawson Tait's operation for lacerated perineum "is approved of or employed by any gynecologist in your (our) classic city." I can answer his question by saying that I have performed it three times during this past winter, twice with the most gratifying success.

I saw Tait do the operation in his usual rapid style in 1886, and described it in my report of my European trip. (See "A Glimpse of Laparotomy in Europe," *American Journal of Obstetrics*, September, 1886, p. 926.) But I did not perform it, being fairly well pleased with my results with the time-honored Emmet's and Simon's operations. Not until I read Sänger's enthusiastic description and recommendation of Tait's method before the Association of German Physicians, at Wiesbaden, last September, did I decide to employ it on the first favorable case, which soon presented itself in a private patient with a very deep complete laceration. I found no difficulty whatever in splitting the recto-vaginal septum, or introducing the sutures, of which I used five, silver wire, and the Peaslee needle being employed. The bands were moved on the sixth day, the sutures removed on the fourteenth day, and perfect union, with complete retention, found to have been secured. Time of operation was twenty minutes; but I could, with a little haste, have done it in fifteen. The skin was adapted by catgut sutures.

The second case was a hospital patient, with incomplete laceration. Here, also, wire was used, and a complete success achieved. The thickness and strength of the perineum in both cases by far exceeded that of the other methods. The ease, rapidity, and success of the method enchanted not only me, but my assistants and spectators, and I briefly reported my results at a recent meeting of the New York Obstetrical Society. (See *American Journal of Obstetrics*, January, 1888, p. 74.) But there was another and less pleasing side of the question. The splitting of the recto-vaginal septum and of the labia forms a deep, broad wound, from which septic infection might take place. Last December a patient presented herself at my office with a large complete laceration of the perineum. I admitted her into Mount Sinai Hospital, and on December 28th did Tait's operation, under the most careful antiseptic precautions, irrigating the wound frequently with a 1 to 10,000 sublimate solution. Deep silkworm gut and superficial catgut sutures were used. The patient had a slight temperature, and complained of much pain on the next day, but as there were no local evidences of inflammation I attributed the symptoms to nervousness (she was very hysterical) and reaction from the operation. I was then suddenly taken ill and confined to the house for three days. A messenger sent to the hospital brought me the news that the patient had a slight temperature, but did not seem very ill. But as soon as I saw her, when able to go out, on the fifth day after the operation, I recognized septic infection, and at once removed the stitches. A large yawning, sloughing cavity presented itself, which was diligently and frequently irrigated, and the patient stimulated by all possible means; but she died of a low form of septic poisoning on the tenth day after the operation. Out of several hundred perineorrhaphies performed after the old method no such accident, indeed no febrile reaction had occurred to me. I do not see how I could have operated more aseptically; it is true, the stitches should have been removed sooner, and would have been had I been able to see the patient. But sepric infection ought not to have occurred at all. I have heard of its taking place in the practice of other operators, but I had so far escaped, and I did not wish to destroy the success of the operation when septic infection was yet doubtful. Still, the fact remains that so deep a wound into so highly absorbent tissues may be more liable to septic influences than the more superficial wound of the old operations.

---

[1] As to food—I have been so often informed by intelligent and observant patients that oatmeal gruel, rather salty, taken often and in small quantities, has afforded them more relief and less discomfort than any other article, that I cannot resist their evidence as to its value as an article of diet in these cases.

My confidence in Tait's method is, however, so strong that I propose to perform the operation next week; but I shall most carefully watch for a rise of temperature, and rather remove the sutures early than risk the life of my patient from septicæmia. I would add one caution, and that is, not to divide the recto-vaginal septum to a greater depth than half an inch, which gives a large enough surface for union. PAUL F. MUNDÉ, M.D.

30 WEST FORTY-FIFTH STREET, February 13, 1888.

INSUFFICIENCIES OF THE OCULAR MUSCLES.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your issue of February 4th appeared a letter of Dr. George T. Stevens, in which occurs the following sentence: "Will Dr. Loring point us to a single instance reported by von Graefe, or any of those whom he has named, including himself, in which tenotomy of either the superior or inferior rectus was done in a case of non-strabismic insufficiency?" The writer further says: "Quite a number of well-informed oculists would be glad to see that report." For the gratification of Dr. Stevens and quite a number of "well-informed oculists" I take the liberty of sending you the notes of the following case: Marie Zalenska, of Warsaw, came to von Graefe's clinique May 15, 1870. Patient had of the right eye, myopia $\frac{1}{36}$, $V = \frac{12}{xxx}$; of left eye, myopia $\frac{1}{5}$, $V = \frac{12}{xx}$. Insufficiency of the interni in 8″ of more than 18°; in 10′ of 9°. Insufficiency of the right superior rectus of 4°. On May 18th a tenotomy of the left external rectus was made, with a conjunctival suture, to diminish the operative effect. On May 20th there was in the position of election dynamical (lateral) equilibrium. On June 2d there was in the middle line dynamical equilibrium. The insufficiency of the superior rectus was revealed only when the light was held on the side of the operated muscle. On June 9th the insufficiency of the superior rectus (patient wearing glasses correcting the myopia) was between 5° and 7°. On June 15th patient wore before the left eye $-\frac{1}{6}$; prism of 20° base upward before the right eye. With these glasses patient had for all distances binocular vision. On June 18th a partial tenotomy of the left superior rectus, leaving a portion one millimetre wide of the innermost muscular fibres, was made. On June 20th the insufficiency of the superior rectus was corrected.

These notes of this case I made at the time, as was my duty as assistant of Professor von Graefe. Von Graefe was not a man to publish individual cases. He made wise generalizations from his vast experience. The operative treatment of dynamical strabismus of the lateral as well as vertical working muscles has been the common property of all competent ophthalmic surgeons for, at least, twenty years. If von Graefe failed to report such a case as this, it was because the case itself was one of not infrequent occurrence. Should the recital of such cases interest the readers of THE MEDICAL RECORD, I will very gladly transcribe others from my record-book of von Graefe's clinique, and might add to them others which have occurred in my own practice.

RICHARD H. DERBY, M.D.

LAPAROTOMY OR ENTEROSTOMY?[1]

By ROSWELL PARK, M.D.,

BUFFALO, N. Y.

Almost without exception every writer who has discussed this question has emphasized the fact that as between the operations of laparotomy and enterostomy in obscure cases of acute intestinal obstruction the surgeon is called upon to decide a matter of the greatest perplexity and most serious importance. On the one hand, the abdominal section offers about the only prospect of overcoming the obstruction, while, on the other hand, it is certainly a terribly grave ordeal to which a patient in this condition must be submitted. Enterostomy is a less immediately dangerous procedure, and is, furthermore, an operation of expediency rather than of absolute cure.

Granting, then, as I am sure all will, the paramount importance of the question as between the two, and the impossibility of giving a perfectly satisfactory quick reply, let us see to what extent it may be definitely answered. Such weighty considerations as may assist in a decision are not to be hastily reviewed. It by no means falls to the lot of any one man to enjoy such a sufficient experience in this matter that he can consistently lay down succinct rules for others to follow. It seems to me that this problem can best be solved by a consideration of the opinion of the wisest and most experienced men of our day, and that this course will guide as safely as a study of numerical statistics which lack entirely a personal element. So without wishing in any respect to belittle the study of percentages and of mortality-rates, whose value I fully appreciate, I have preferred to lay before you a summary of the opinion of some of the most noted living surgeons, thinking in this way best to further the object of this notable discussion.

First of all, it is generally accepted that when a tumor is distinctly felt there is no surgical relief save by abdominal section, which should accordingly be made unless the patient's general condition absolutely contra-indicates it. Still, blind observance of this rule will surely bring disappointment, and even a liberal interpretation of it is not always a happy one. Thus in one case I was called to a case of acute obstruction simply for the purpose of operating for its relief. With grave doubt as to its surgical propriety I yet opened the abdomen and found malignant trouble in the pelvis. I made an artificial anus low down in the linea alba, but with only very temporary relief. In another instance I was summoned a hundred miles to afford surgical relief. It was evident the patient was suffering from a malignant ovarian tumor. Yet she was suffering terribly, and absolutely insisted upon operation at all hazards. Her apparent body-strength was a source of serious error, since I mistook her resolution and courageous or desperate persistence for vital power; she died before the operation was completed. But my experience has been unusually unfortunate, and one may be excused perhaps for being overpersuaded by the dying appeals of victims undergoing this torture.

Schramm[1] takes the ground that when the indications are not clearly for enterostomy and against laparotomy, the latter should be selected. He comes to this conclusion partly as the result of his own observations, partly from a careful study of recorded results. Still he does not deny the ease and readiness with which enterostomy is done, and contents himself with a reminder that more than once the gut has been opened *below* the obstruction. He claims, also, that Nélaton's operation is now perfected, while in the technique of laparotomy much improvement may yet be made.

Rydygier[2] quotes Czerny's[3] dictum that one should only perform laparotomy in cases where the vital powers are still capable of withstanding shock in severe form; where the abdomen is still soft and not too distended; and where, upon diligent examination, after the anæsthetic has been given, still no exact notion can be gained as to the locality and nature of the obstruction. He thinks that if this be closely adhered to we shall very seldom be found opening the abdomen. Still, while not disputing its wisdom in general, he expresses a hope—in which we may all join—that these cases shall, as time goes by, either be more accurately recognized in their incipiency or be turned over to the surgeon while there is still a fair chance for the benefits to be gained by a thorough operation.

In his estimation the only cases suitable for enterostomy are: 1. Those where the gut is firmly pressed upon by tumors, and where an artificial anus may relieve the most urgent symptoms, and prepare the patient for a more radical measure later. 2. Those where the intestine has undergone such a partial twist that its nourishment is endangered, and where, it may be hoped, that after evacuation of its contents it may untwist itself.

Madelung[4] prefers enterostomy for the majority of cases of ileus calling for operation, at least until better means of diagnosis are afforded, and bases his preference on the better results he has obtained by it.

He alludes to the difficulty of locating the obstruction, even after laparotomy, and says that in those cases where he has failed to find it he has asked the pathologists who have made the sections to repeat the same manœuvre, and has seen them fail after twenty minutes' search with the hand introduced through the wound. He is, furthermore, opposed to any handling of the intestines, being convinced that the danger of septic peritonitis is thereby enhanced.

Madelung's own plan of operation is to begin with a small incision in the abdominal wall. Through this he makes such investigation as is possible with reference to the immediately adjacent intestine. He then pulls out a loop of distended gut, so that it doubles on itself. This is held out of the wound by two strong silk threads passed under the loop and through its mesentery. The patient is then turned on his side, the knuckle of intestine and the wound protected by iodoform gauze, and the gut deliberately incised so that all its contents can escape, their flow being encouraged by insertion of a soft catheter. He then waits for fifteen minutes or so, during which time the anæsthetic is, perhaps, intermitted. When nothing more escapes, the wound in the intestine is carefully closed with fine suture. Now, after carefully cleansing the parts and throwing away the gauze packing, the original abdominal opening is enlarged. If an obstruction is discovered, it is treated as may seem best; if nothing can be discovered, the intestinal loop first utilized is found again by means of the silk threads which have not yet been removed; this is then sewn into the abdominal wound, and reopened where first incised. Thus the artificial anus is produced.

---

[4] Archiv f. klin. Chir., xxxvi., 283.

This method of Madelung's certainly has much to commend it, and deserves to find ready acceptance.

Schede's [1] recent paper is almost entirely devoted to the surgical treatment of ileus. He commences it with the most undeniable statement that the fate of those suffering from ileus depends entirely on an early diagnosis. He also lays stress on this most practical point that there is, perhaps, no other acute disease in which the patient's ability for resisting shock so rapidly vanishes. But a short time suffices to so weaken him that even the mildest form of surgical relief cannot be borne. He also insists that the hours spent in experimenting with drugs, with enemata, and with washing out the stomach are not only too often wasted, but leave the case entirely beyond surgical help. To be sure, once in a great while we see such a case recover without operation, but it is a most rare event, for which one cannot afford to wait; most of these cases consist, in fact, of volvulus of the sigmoid flexure and intestinal obstruction in small degree. The more sudden and complete the occlusion the greater the constriction, and the more probable that it is absolute. In such instances every effort to palliate or to temporize is to the greater jeopardy of the patient. It is in these most severe cases that, in his belief, the prognosis after laparotomy is the best. The condition of collapse is rather one of shock, and not an undermining of vital power, consequently is not beyond possibility of reaction. But even the laparotomy which he would favor is to be done only when the location of the obstruction is pretty clearly made out, or when the general indication is that it can be quickly overcome.

Schede, while not absolutely opposed to such extremely radical measures as Kümmell favors, yet prefers a small incision. He, too, reiterates the statement that the question as between laparotomy and enterostomy is one of the most urgent, yet difficult, ever presented to the surgeon. In many cases, nevertheless, he thinks there can be but little room for doubt, and that the formation of an artificial anus offers the only hope. For this purpose he utilizes, if possible, the cæcum. In many cases of ileus it is above the seat of obstruction, while it is best adapted for artificial feeding. It also enables one to meet the indication of opening the intestine as low down as possible. If the cæcum is found empty, then the most accessible loop of distended small intestine can be grasped.

He prefers an incision two inches above, and parallel to, the right Poupart's ligament, and he carefully unites the parietal peritoneum with the skin before attaching the gut, a technical point of great value. Having had a most unpleasant experience in postponing opening of the gut itself he advises to do it immediately. He particularly emphasizes that it seems to him a little-known and scarcely appreciated fact that enterostomy always has not only an immediately palliative effect, but it often exercises an absolutely curative influence upon the obstruction, be this what it may, so that later a normal, permeable condition of the bowels is brought about. Soon a small quantity of fæces escapes by the natural channel again, and later this amount increases, till the artificial anus may even close spontaneously.

A beautiful illustration of this I have seen in the practice of my colleague, Professor Mann, of Buffalo. He was called out of town to operate for obstruction of the bowels of severe but uncertain nature. He made an exploratory laparotomy, but was totally unable to discover any internal condition which could account for it. He accordingly made an artificial anus. The symptoms of strangulation at once subsided. Later she came to our hospital for closure of the fæcal fistula, where I saw the case with him. Partly as the result of a plastic operation, and partly spontaneously the opening was closed; but it was made quite apparent before its closure that the bowel below was cleared of obstruction.

It has happened once to me also to open the abdomen for intense symptoms of strangulation and to discover nothing. I very much regret, now, that I did not make an enterostomy before closing the abdominal wound.

But the German surgeons are not all so much in favor of enterostomy. Kümmell, like Heald and Heiberg before him, has advised making a large opening when doing laparotomy. This, of course, facilitates exploration but complicates in some degree the case. Kümmell [1] claims that perityphlitis is perhaps the only absolute contra-indication of laparotomy. Peritonitis is usually a sign of septic trouble or of perforation, and is consequently secondary. He compares laparotomy for ileus to suprapubic lithotomy, which permits such inspection as is without it impossible. It permits, further, closure of a perforation if one exist, and as much disinfection of the abdominal cavity as circumstances may justify. Enterostomy alone permits none of these measures, and is not always successful; it further usually necessitates a later operation, which is not free from danger.

To be sure, in doing laparotomy, one must contend with the length of the operation, the uncertainty of even finding the cause of the trouble, and the difficulty in returning the intestines to place. Kümmell is extremely radical in his section method, since he would make the incision at once extend from sternum to pubis, and claims that the discovery of the lesion is thereby greatly facilitated, and the duration of the operation actually shortened. Indeed it is doubtful if surgeons will at once accept his operative method as in the end the safest; perhaps not generally until his results can be compared with those of others.

No one in Great Britain speaks on this subject with greater authority than Mr. Treeves.[2] He advises against primary enterostomy, which, *he* says, is at best a palliative measure, not founded on sound surgical principles, carried out independently of diagnosis, done in the dark, and leaving the cause of the disorder untouched. He calls attention also to the fact that the opening *may* be made so high up as to lead to subsequent emaciation and death from starvation. The accumulated material between the new opening and the rectum may be the cause of great distress, or the obstructed or twisted loop may go on to subsequent gangrene. While there is no denying the force of these statements the improbability of the frequent occurrence of any of these untoward events must not be forgotten.

The Société de Chirurgie de Paris during the past year held a long and lively debate [3] concerning the merits of the great question before us—a debate which put its individual members on record without shedding any particular light on the subject. Verneuil took the ground that when one *can* distinguish with any accuracy the nature of the obstruction, he should make the operation as radical as possible. This being impossible, the surgeon is compelled to address himself solely to meeting the immediate indication, and must, therefore, open the intestine at the most practical point. Le Dentu would, as far as he could, limit enterostomy to those cases where the obstruction pertains to the intestine itself. Le Fort and Richelot were heartily against laparotomy in all uncertain cases, while Terrier and Trélat were its advocates, particularly since the one did not prevent the other if found advisable.

Within the past few months Rochet [4] has written at length on these subjects. He alludes to the recent experiences of French surgeons, to the uncertainty of diagnosis, and to the bad results of secondary enterostomy. He believes that when neoplasms and impaction can be excluded the obstruction must be considered to be caused by volvulus, invagination, or adhesions; these indications being reasonably clear, he considers laparotomy to be required.

But when one is absolutely in the dark, Rochet would have him at once proceed to enterostomy. When a diagnosis of tumor or stricture can be made, then an enterostomy or a colostomy are positively indicated.

That the road to success in these cases is bestrewn with stumbling-blocks may be made still clearer by two or three illustrative cases. In Rydygier's fourth case[1] he made a laparotomy and found a loop of ileum bound fast in the pelvis to the results of a perforating ulcer of the rectum. He made an artificial anus, but regretted that he had not contented himself with an enterostomy in the first place.

Waldenström[2] had the case of a child, aged twenty months, that presented at the anus a tumor easily recognizable as an invaginated colon. All efforts at reposition failing, the colon was opened in the loin. Even then reduction was not possible. After death it was found that a second ileo-colic invagination existed.

Brown[3] has reported the case of a boy, aged fourteen, in which the diagnosis of intussusception was made. A tumor was felt to one side, and an incision was made directly over it. The lesion was easily found, but reduction was impossible. A colotomy was then made, but the small intestine was found to have so far filled the colon that nothing was gained. Death ensued in six hours. While Brown regretted that he had not opened the abdomen in the middle line, it seems to me, rather, that his regret should have been that a laparotomy was made instead of an enterostomy.

These, as well as numerous others of equal interest, may be found at considerable length in Braun's most valuable article,[4] to which those interested are referred.

To be sure, Bulteau's statistics[5] of twenty-one cases of acute invagination treated by laparotomy, with eight recoveries (= 38 per cent.), are encouraging; but the division of our subject precludes my consideration of this view of it, and I must leave that to abler hands.

So far, then, as a careful study of the recent literature of the subject would permit conclusions to be drawn, they are:

When a case of acute obstruction is seen *very* early an exploratory laparotomy may be justified.

When a case is seen very late, enterostomy is probably the only justifiable operation.

Laparotomy is especially indicated when the nature of the obstruction is recognized or made reasonably evident; when a small tumor indicating intussusception is made out; when the obstruction is caused by neoplasms which can be removed; when the condition of the peritoneal cavity demands washing out or drainage.

Enterostomy is especially indicated when no idea can be formed of the nature of the obstruction; when the malignant element precludes hope of permanent benefit; when the abdomen is particularly tympanitic; when the patient's power of endurance has been undermined by the severity of the disease.

To put this somewhat differently, laparotomy is the more radical and surgical measure, but somewhat the more dangerous. Enterostomy is the safer and quicker, causing little or no shock, but entailing certain very disagreeable sequelæ, suitable for all desperate and some more favorable cases. Abdominal section should never be done *in extremis;* enterostomy may be. Since many cases are only seen by the surgeon in this terrible condition, the lesser operation will still find a wide applicability. It is accompanied by scarcely any danger of peritonitis, and may even be done under cocaine, so that the shock of an anæsthetic may be avoided. Cases die after laparotomy as the result not merely of the disease; an enterostomy, on the contrary, complicates the case, if at all, in extremely small degree.

These conclusions, it appears to me, have a value that no criticism can diminish. But beyond these one is confronted by the complexity of the circumstances attending individual cases, which only the attending surgeon can estimate, and therefore to presume to go further is to take the ground that rules must rise superior to circumstances, a position quite untenable among those whose experience or ability qualify them for this kind of abdominal surgery.

THE "ORAL WHIFF."

By WILLIAM S. CHEESMAN, M.D.,

AUBURN, N. Y.

The article entitled "An Undescribed Arterial Murmur" in The Medical Record of November 5, 1887, reminded me forcibly of another murmur synchronous with the pulse of which there is no satisfactory description in the literature accessible to me, and with which none of the well-known diagnosticians whom I have addressed on the subject are familiar. Perhaps it can be best portrayed by an account of several illustrative cases.

Case I.—A gentleman, aged thirty-three. Had always enjoyed excellent health, and was quite athletic during early manhood, but inherited a neurotic temperament. Had smoked considerably, and been much harassed by business during the season of 1886. Went shooting early in September, and in pursuing a grouse through heavy underbrush, became considerably blown. Sitting upon a fallen tree to recover wind, he observed that the sound of his breathing, particularly in expiration, was intermittent, giving a puff at each beat of the heart. The expired air, instead of leaving the mouth in an even, prolonged current, came in a series of whiffs which may be represented quite accurately by the sounds *huh, huh, huh, huh.* These were loudest at the commencement of expiration, and became fainter toward its close. Inspiration was similarly broken, but the interruptions were less marked. As the heart's action quieted down, this pulsation of the breath became less and less noticeable, till it finally ceased. A second run, however, reproduced it exactly as before. At no time was the subject conscious of any pain, or shortness or difficulty of breathing. As he had never observed the phenomenon before, even during the exertions of his old athletic work, he sought medical advice.

Examination of the heart discovered no abnormality whatever. Its sounds were clear; no murmur could be found over any part of the chest. The action was, however, rapid, and complete abandonment of tobacco and coffee was advised. The respiratory sounds were also even and regular. I could not detect the puff which was described, but as the patient said that exertion would bring it back, I asked him to run up and down stairs several times. The sound was then plainly heard by the ear held about a foot distant from the patient's open mouth. I listened with the stethoscope over the chest, but could not distinguish it there at all. When the instrument was applied along the trachea, however, it came out loudly, and had the characters already described. Drummond's "oral whiff" as a sign of thoracic aneurism came to my mind, and therefore, though there were neither symptoms nor physical signs of this disease, I re-examined for it carefully and repeatedly, but with an entirely negative result.

This subject now enjoys excellent health, but exertion always reproduces the puff in his breathing. When carefully listened for, it can also be heard even when he is at rest. He has often heard it faintly *when lying in bed at night.*

Case II.—A young man, aged twenty-four. Gave a history of neurasthenic symptoms. Had been aware of the respiratory puff ever since boyhood. In character it corresponded perfectly with that described in Case I. The subject had no sense of shortness of breath, and heart and lungs were sound.

Case III.—Very nervous lady, aged thirty-three. Puff well marked; heart-sounds normal. Had never observed the breath-pulse herself.

Case IV.—Gentleman, aged forty-five. Heart and pulse normal. Had neurasthenia ten years ago, and at the time of examination was excited over a political contest. Had never observed the sound, though it was plainly audible.

CASE V.—Workingman, healthy in all respects. Whiff well marked, but never detected by himself.

I have often examined patients for this peculiar pulsatile breath, but have found it only in the cases narrated. Those having larger clinical opportunities might, doubtless, meet it frequently if they sought for it. But it was never alluded to by any expert under whose tuition I have been, nor have I since found any physician who knew aught about it, nor any work on physical diagnosis which mentioned it. The Index Catalogue of the U. S. A. Library contains no reference to it. The only account which I can find is in descriptions of Drummond's "oral whiff," where it seems to be looked upon as a familiar fact. But, considering the sort of men who have professed to me their ignorance, it certainly cannot be an every-day matter. To them, as well as to myself, it was a puzzle—which is my reason for describing it here.

Why it occurs in so few subjects and not in others I cannot explain. In my small experience it has usually been associated with a distinctly neurotic constitution. Nor is the mechanism of its production clear. Two explanations have occurred to me. When one listens to the sound along the trachea, it seems as if it must certainly be due to interruptions of the column of in-going and out-going air by the intermitting pressure of some part of the circulatory apparatus; the entering current being simply retarded at each systole, the emerging current being alternately obstructed, and then liberated under accumulated pressure. This is the explanation sometimes given of the "whiff" in cases of thoracic aneurism. No such compression of the air-passages could take place, however, without dyspnœa. Both in health and in aneurismal disease it seems more likely that the sign described is due to the fact that each rise of intra-thoracic pressure attending the aortic expansion so increases the expulsive force of expiration that the sound of the air rushing through the narrow *rima glottidis* is momentarily intensified into a puff.

The conditions may be roughly imitated as follows. Over one extremity of a glass tube tie a piece of sheet rubber, having a slit cut in it from side to side of the tube. This represents the vocal cords. To the other extremity attach the double atomizer bulbs. After distending the reservoir bulb, allow the air to escape slowly through the artificial *rima*. In so doing it will make a blowing sound. While it is passing, compress the reservoir intermittently. At each added *vis à tergo* the sound will rise to a distinct puff, which, allowing for necessary faults in the instrument, and for the absence of resonating chambers like the pharyngeal vault and the nasal corridors, bears a close resemblance and analogy to the "oral whiff."

The value of this whiff as a sign of intra-thoracic aneurism must depend on its association with other physical signs of that disease. It would certainly seem that any physician accepting the usual statement that the "oral whiff" occurring during physical and mental quietude is of itself evidence of aneurism (see Pepper's System of Medicine, vol. iii., p. 811) would inflict needless alarm upon his patient.

A PHYSICIAN PROSECUTED FOR ASSAULTING A BABY.—A physician in Berlin was requested to prescribe for a boy, four years of age, for some slight ailment, but the child screamed so that it was impossible to examine him. After trying for a long time to quiet him, the physician lost his patience, and gave the boy two or three slaps with his hand on the nates. The mother was very angry and took the child away at once, and in a few days brought suit against the medical man for assault upon her boy. It was shown that no injury had been inflicted upon the child, and the physician was acquitted, the court holding that he had acted for the good of the patient, and that the punishment was inflicted with the best intentions.

DUPUYTREN'S FINGER CONTRACTION.[1]

FURTHER REMARKS ON THE THEORY OF ITS NERVOUS ORIGIN.

By ROBERT ABBE, M.D.,

SURGEON TO ST. LUKE'S HOSPITAL, AND CONSULTING SURGEON TO THE HOSPITAL FOR THE RELIEF OF THE RUPTURED AND CRIPPLED, NEW YORK.

THE infrequency which Dupuytren's contraction of the palmar fascia is met with by most practitioners, and the scant literature of this interesting subject, together with its uncertain or unsettled etiology, lead me to offer some observations based on my personal experience with it.

No one who has ever operated upon one of these contracted palms, traversed by dense bands of glistening fibrous tissue, questions the locality of the contracting tissues. It is essentially a hyperplasia of the palmar aponeurosis fibres, with involvement of the areolar connective tissue of the palm, often taking in the skin also. But what cause can be assigned for its commencement is yet a moot point. It comes with mysterious quietness, and never is spontaneously arrested. Must we conceal our ignorance of its cause behind the word idiopathic hyperplasia, or can we definitely ascribe another? Gout has been commonly received as the most probable factor, but with this I have never been satisfied, for reasons I will soon give. During the past seven years I have observed not less than forty patients with this malady, of which I have private notes of at least twenty-five, and upon the study of these I venture to offer some points which seem to me of importance.

In 1884 I read a paper on this subject before this Academy of Medicine (*New York Medical Journal*, April 19 and 26, 1884), in which, after reviewing it, and reporting ten cases I had been studying, I advanced a theory of its causation, which to me was more satisfactory than the vague assumption of gout which Mr. Adams, of London, and some others think can be assigned to most every case, and which, for want of a better, has been accepted by authors generally.

My conclusions resulted in the following working hypothesis to explain the disease.

First.—A slight traumatism of the palm, often entirely forgotten.

Second.—A spinal impression produced by this peripheral irritation.

Third.—A reflex influence to the part originally hurt, producing insensible hyperæmia, nutritive-tissue disturbances, and new-growth, shown in the contracting bands of fascia and occasional joint-lesions resembling subacute rheumatism.

Fourth.—Through the tense contractions a second series of reflex symptoms, neuralgias, general systemic disturbances, and a reflection of the trouble to the corresponding part of the opposite hand.

Since the publication of that theory I have often been asked if subsequent cases have confirmed it.

I may now say—decidedly—yes! for the following reasons:

First.—Very few cases of Dupuytren's contraction have specially strong hereditary or personal predisposition to gout, and many have no taint whatever of either rheumatism or gout.

Second.—No case I have yet seen has had both hands affected simultaneously. An interval of from a few months to several years occurs between them.

Third.—The neuroses of scar tissue in various parts of the body are universally recognized by surgeons and specialists, and are analogous to those accompanying Dupuytren's contraction.

Fourth.—The neuroses of which I shall speak are secondary to the development of the palmar bands, and can be started up oftentimes by hurting these.

Fifth.—The neuralgias and neuroses are usually relieved by operation, oftentimes as if by magic.

---

[1] Read before the Surgical Section of the Academy of Medicine, February 13, 1888.

On these five points I will now narrate my experience.

First, as regards hereditary taint and a personal predisposition to gout, that are assigned as coincidences in the great majority of cases of this affection by two of the many observers. In my earlier cases I found no corroboration of this theory, and in my last twelve there is a striking absence of taint, except as follows.

In one patient of these twelve, the man's father had been troubled with rheumatism "all the time," and there was a family tendency that way, though his mother had not suffered from it.

In another case, a German laborer, there was no inheritance; but the patient himself had had a short two-weeks' attack in one arm and leg some years before I saw him.

In a third case, a lawyer, who had never had rheumatism himself, had one brother who had been subject to it, but he was the only one out of a family of ten children.

In the other nine cases (they were all males), there was no hereditary or personal taint. Some were thoroughly conversant with their family history, and spoke most emphatically in the negative.

I have been endeavoring to reconcile my observations with those of Adams and Keen, who think it due to gout. The clue to their suspicions of this taint I find in a sentence of Dr. Keen's, which reads: "The large majority of all the cases I have seen had enlarged and tender finger-joints, the seats of more than suspicious pains." Now it is eminently true that, coincident with the palmar irritation, there is often a train of symptoms of nervous origin frequently simulating rheumatism, *and not only absent before the palmar disease came*, but disappearing, as I shall show later, when the disease is cured.

It would be difficult to review a dozen cases of any other disease in which there was less ancestral or personal history of the commonplace rheumatism, or what is rarer in this country, but of which the English and French writers speak so often, namely, gout. Therefore I feel we must look for other origin than this, and would repeat that, more than ever, I believe sincerely rheumatism has little or nothing to do with its causation.

It would be reasonable to expect that, if it depended on such a constitutional cause, it would appear more or less simultaneously in both hands, or that the feet would also suffer; while if it originated from injury sustained by one palm, and appeared long after in the other, often with coincident neuralgias following the upward course of the nerves from the first well-established trouble, and which were repeated in a similar form in the opposite hand, we would find some corroboration of the theory I have advanced.

As a matter of fact, we do find that the contraction in one hand always precedes that in the other by from a few months to many years. In one case, the right existed twenty years, the left eight. In another, the right, twelve; the left, seven. And so they usually are found, with several years between.

In one old gentleman's case, one hand had been in trouble twenty years before it affected the other. Thus a chronic nerve irritation in one scar is—more or less—slowly reflected to the opposite side.

As regards the third point, scar-tissue in any part of the body may give rise to neuralgia in distant places. There are few physicians who have not seen painful sensations, radiating to a distance from a cicatrix, entirely relieved by excision of the scar. I have seen a number of such instances.

I recall one, several years ago, in a very intelligent old gentleman, brought to me by Dr. A. A. Smith, for intractable neuralgia of the entire arm and shoulder, the sole cause of which was a small, hard, linear scar of the palmar side of the last joint of his middle finger, cut by a falling window sash. I excised the scar, and the neuralgia entirely disappeared.

Some years ago I assisted Dr. Weir in removing the depressed cicatrix of an old bullet-wound of the thigh in a gentleman, the victim of a vicious neuralgia of the foot and limb. He was completely cured by the operation. Twice I have relieved neuralgia of the leg by cutting contracted fascia beneath the toes.

These are well-recognized surgical incidents, and strikingly analogous to the pains of many cases of Dupuytren's contraction.

Fourth.—There are associated with Dupuytren's contraction, in more than half the cases, a various list of neuroses, which constitute an unwritten chapter in the disease. To one who sees a case but seldom, many of these would not for one moment be considered as related to the palm trouble, at least in the sense of sequel. In some patients there is apparently no pain or sensation associated with it. In my experience, however, this is not usual, and the victim suffers from what he supposes to be another disease, which, however, is intimately related to the hand.

In my former paper I related one of the most striking cases that has come under my observation. It was of a man suffering for years from persistent and severe rhachialgia of the lower dorsal vertebræ, for which he had been blistered, cauterized, ice-packed, and dosed with drugs by distinguished medical men. The backache was instantly relieved by operation on the contracted fingers, and never returned.

In the case of a cloth-cutter, with both hands affected, who had given up work on account of the unbearable pain of the palm, especially the right, which was second to be affected, and which he could scarcely lift to his head or touch in the palm without suffering, I operated first on the left only—it being the tighter—and at once *the pain left the opposite hand entirely*, so that he could swing it above his head, brush his hair, lie upon it at night, and do many things that formerly caused great suffering. He remained cured.

A third case, already reported, with pronounced Dupuytren for nine years, had had, several times during each year of this period, attacks of painful subacute swelling of the fingers and joints of the affected hands, which kept him awake nights, and caused increasing depression of spirits. He had abandoned business in consequence. Since operating on his hand four and a half years have elapsed, during which he has never had return of the pain. He is now in perfect health and spirits.

A fourth case—a physician with numbness and tingling in the palm when the contracting band was in its infancy—had, after the band grew, a neuralgic pain, darting occasionally from the palm up the forearm. This subsided six months later, when the opposite hand began to contract, and then the pain stayed altogether in that one.

Fifth case, also reported: Double Dupuytren's contraction. Has a burning sensation in the palm. No neuralgia.

Sixth case, also reported: A butcher had tingling sensation, persisting for two years, in the adjacent sides of the ring and little fingers, but no neuralgia. During the four years of his Dupuytren, however, he had had a writer's-cramp of the thumb, little, and ring fingers of the affected side, so that after writing a few moments cramps would seize them, they would stiffen up, and he would have to drop his pen and pull them straight.

I will make one more extract from my published cases of an interesting form of neuralgia associated with this contraction, which existed seven years in one, and four years in the other palm. For three years the patient had had numerous attacks of cervico-brachial neuralgia, lasting ten days. Each paroxysm of pain during this time was relieved by folding his arms, and tightly squeezing them together. During the same period he had, every few weeks, attacks of sudden neuralgia of the right palm, repeated at a few minutes' interval for several hours, and eased only by pressing the opposite thumb into the affected palm. He also had occasional neuralgia of the right leg and thigh, and hyperæsthesia of the back, painful to the touch of a towel. I regret that at the time he could not leave his business to be operated on, and has since passed from my sight. But I have no doubt the neuralgias and hyperæsthesia, one and all, would have been relieved by proper division of the contracted palmar bands.

Of my later cases, now published for the first time, I will narrate such as bear on this most interesting feature of the matter, omitting details irrelevant to this point.

Hugh McG——, aged sixty-two, truck driver. Dupuytren's contraction twenty years in the right, and eight years in the left palm. Six months before being seen began to have severe pain in the radial side and back of the left wrist. It was a burning pain, as of a coal burning deep inside the wrist. The latter became quite weak, so that he could not do a day's work during the four months prior to operation. The pain was worse at night, coming on when quiet in bed, and giving a sense of burning that caused him to keep it exposed on top of the bedclothes. He could not lie on his left side at all, without, as he expressed it, " squealing with pain." Sometimes this would dart up the arm to the shoulders, neck, and side of the occiput, so that he could hardly turn his head to that side for the pain in the neck. This paroxysm would usually last several hours.

He had most typical disease in each palm. In 1884 he came under the care of Dr. W. T. Bull, who kindly invited me to operate on one hand by Adams' method of subcutaneous division, while he operated on the other by open section of the bands, to compare the relative merits of the two methods. I chose the left, because it was the older trouble and the seat of all the pain. I made twelve subcutaneous cuts on three cords, and released the fingers thoroughly.

From the moment of operation he had not a particle of pain in the wrist or arm, and never afterward lost a moment's sleep from the hand. He soon resumed work, and I saw him, long afterward, perfectly well and without recurrence. He remarked that " no one ever had such wonderful relief."

In March, 1885, Dr. M. C——, aged forty-seven, appealed to me to relieve him of Dupuytren's contraction of twelve years in the left, and four years in the right hand. It resulted from a tight ring, which had to be cut off the left hand twelve years before, and which was at once followed by the commencing trouble.

His case exhibited the following striking neuroses: On two occasions during the past four years he has had an attack, lasting several days, of " battery-shock " sensation in the left ulnar nerve. When I saw him he had been having, for eight days, constant and severe neuralgia of the left ulnar nerve, worse sometimes in the forearm, sometimes in the arm toward the shoulder, and again in the pectoral region, like an angina pectoris. Part of the time it was a dull aching pain, and at others an acute neuralgia, for which he had had to resort to considerable quantities of morphine for relief. I operated under cocaine anæsthesia. He was completely relieved at once, and remains so at the present time.

The next case displaying a neurosis was in an old gentleman of seventy-two, with classic cords in both palms. For ten years it had existed in the right hand, and somewhat less in the left. He had occasional pains about the left shoulder, but that was nothing to him comparable to a notable sensation present most of the time in the right arm. From the shoulder down to the fingers there seems to be, to his sense, a great increase in size, as if it were distended to twice its natural bulk, giving a strange, unnatural feeling.

I excised, under cocaine, the entire well-marked and long band in the right palm. The delusive sense of increased size slowly left the arm. That was two years and a quarter since. I saw the patient a few days ago, and he remains free from pain or sensations. The cicatrix is without the slightest sign of return of trouble, and the play of the fingers perfect. By coincidence he volunteered the statement, which is of interest in this connection, that the knotted cord of the left little finger (never operated on), which had been rapidly getting worse during the year prior to my operation on the opposite hand, was now getting softer. Comparing it with drawings made at the time I could corroborate his statement.

Now as the trouble in this hand was a sequel to the other, is it not possible that curing the right might cause some retrograde action to go on in the left, if, as we see, there is unquestionably sympathy between the two?

In the case of Dr. S——, of this city, seen by me last year, there was occasional pain only in the band itself in one palm.

In the case of O. W——, aged sixty, the left middle finger drawn down, with increasing weakness and pain in the forearm. Operated on by excision of the band. Pain relieved.

In the case of Dr. W——, of Virginia, whom I recently operated on, we have most interesting illustrations of the relation between the contracted palm and the distant pains. This gentleman, in middle life, without trace of rheumatism or gout, inherited or acquired, began to have Dupuytren's contraction three years since. He attributed it to carrying a whip, with heavy loaded handle, pressing his right palm, while in constant hard riding the left hand held the reins tightly. The left first showed trouble, neuralgia being an early accompaniment. The suffering was in the arm, shoulder, and side of the neck. Three months later the right took on the same pain. Both have been growing worse during the last six months, so that he has been broken down in his work. Occasionally, when riding, the neuralgia will attack his shoulder with a sensation as if he were being " clawed." Again, he is often seized with an intense pain at some distant point, as in one thigh or a spot on the arm. The neuralgia is now continuous. Two weeks ago he came to my office suffering as usual from pain, specially in the deltoid and brachial region—both sides. I at once operated, under cocaine, on the worst hand. Before I could get the dressing on the part he assured me the pain had entirely gone from that arm and shoulder. Five days ago, pain having continued unabated on the opposite side, I performed the same operation, namely, the open transverse incision of all the bands in the palm. The relief to the shoulder was complete and instantaneous, as it had been on the opposite. He has since remained absolutely free from neuralgia, and feels like another man.

There are some cases of well-marked bands that have no accompanying pains or reflex sensations, ao far ss we can see. I suspect that the pain depends on the involvement of sensory nerve-filaments by the cicatrix, and that those cases have not entrapped the sensitive nerves at a disadvantage. They are not an argument against the influence of a cicatrix on distant parts, as an insensible play of nervous force can go on without subjective pain, as in sympathetic ophthalmia.

In the only case I have seen where there was a strong family tendency to rheumatism, and where the patient himself had it before the Dupuytren's contraction, I made a clean dissection of the fibrous band, and for ten days everything went well, until a stiffening and subacute rheumatism of the joints of the hand set in, which left a stiffness that has only moderately gone away at the end of a year and a half. The hands were left unstretched after the operation, and the trouble seemed to depend entirely on the patient's constitution. Adams and Keen speak of this incident occurring occasionally. In this patient's hand it was noted that whenever a piece of ice or cold object touched the band in his palm, it sent a severe pain up the ulnar nerve—a further proof, if that were needed, of the intimate relation of the two.

From this recital of painful neuroses associated with, and a sequel to, the onset of many cases of contraction of the palmar fascia, we find new strengthening of the argument for its nervous origin, especially considering the magical relief of pain by cutting the bands, the relief not infrequently extending to the opposite side of the body. In operating I have tried every method. I prefer excision of the band if it is well defined; or if not, and if the skin is much involved and the band matted to the tendon-sheaths, then numerous transverse open sections. These small gaping wounds fill quickly with granulations, or else close by primary union, with a little wedge-shaped clot. The soft scar does not contract, and the wounds are entirely healed in from ten to fifteen days.

I operate preferably with cocaine anæsthesia and Esmarch's bandage. The only dressing on the palm after the operation, and before the Esmarch bandage is removed, should be thick, well-adjusted compresses of damp gauze, fresh from sublimate solution (1-1,000). No iodoform is needed. No stretching of the parts should be allowed for ten days, and then it is rarely needed. Splints may usually be discarded from the treatment as doing more harm than good.

IS IT EVER JUSTIFIABLE TO PROVOKE PREMATURE LABOR FOR THE RESTORATION OF SIGHT IN ALBUMINURIC RETINITIS?

By J. L. THOMPSON, M.D.,

INDIANAPOLIS, IND.

This question is asked by Dr. Thomas R. Pooley, in The Medical Record of January 28, 1888. It was also put by Dr. E. G. Loring, in a paper published in the "Transactions of the American Ophthalmological Society" in 1883, and to the latter Dr. Pooley gives the credit of having first induced premature labor for threatened permanent blindness.

This same question confronted me six years prior to the publication of Dr. Loring's able paper, but my reason for not then reporting it was that I supposed the practice had been more frequent than it now seems to have been, and that it had been written upon, but had escaped me. On October 11, 1877, I was called twenty-five miles distant to see Mrs. J. D——, aged thirty-nine, married several years, pregnant nearly eight months with her first child. Her sight had been failing for nine days, but total blindness did not set in until the day of my visit. The ophthalmoscope revealed a well-marked retinitis albuminurica, with the characteristic exudations in and around the macula lutea and blood-extravasations from the retinal veins. She was a very intellectual woman, short in stature, stout, of apparently plethoric habit, and, with the exception of this trouble, seemingly in good health. Her loss of sight was so complete that she could not discern even the brightest light thrown upon the eyes from the mirror of the ophthalmoscope. The urine contained much albumen. On consultation with her physicians, then present, Drs. Payne and Webb, of Franklin, Ind., I advised the immediate induction of premature labor for the preservation of both eyesight and life. This was promptly done, and in two days the child was delivered, but died thirty-six hours afterward. In a few days the patient could distinguish between light and darkness, then could discern large objects, and in a few weeks sight was fully restored.

She called upon me on December 6, 1877, when I made the following additional record on my books: "The exudative patches have given place to five little white spots in the right and two in the left eye. V. equals $\frac{20}{50}$ right and $\frac{20}{30}$ left eye; can read the finest print at the usual reading distance. Dr. Payne writes that the urine shows but the slightest trace of albumen." The vision has since become quite normal. The woman is now in good health, but has not conceived since her former terrible experience. This patient was very anxious to go to full term, as she and her husband greatly desired children (they having been married so long); and had it not been that total blindness was threatened, no other cause could have induced her to make the sacrifice which she did. My reasons for this step will appear after a brief report of some other cases, as follows:

Soon after my location in this city, seventeen years ago, I was called by a physician to examine the eyes of one of his patients, far advanced in pregnancy, whose sight was failing rapidly. I could not then leave my office, so put it off until after my regular office-hours; but an urgent call for him to the bedside again in the evening caused us to hasten to the house, when we found her in a uræmic convulsion, from which she died in a few minutes.

I saw another similar case on October 6, 1877, with Dr. F. S. Newcomer, of this city. Mrs. M——, aged twenty-seven, became suddenly blind. Dr. Newcomer saw her for the first time before breakfast on the 6th, when she complained of a violent pain in the head; labor came on almost immediately afterward, and she was delivered in less than two hours. I saw her a little past noon, and found, as in my first case, well-marked retinitis albuminurica. She was treated with salines and other remedies, but died in convulsions on the following day.

On July 27, 1885, Mrs. H. C——, aged thirty-five, was brought to my office by her physician, six weeks after her confinement, with the following history: "Had convulsions ten days before parturition, and became totally blind." My record reads: "V. equals O. both eyes; pupils widely dilated; characteristic exudation all around each macula lutea and optic disc; many partially absorbed blood-extravasations in each fundus." The patient called again, January 20, 1886, when nothing was to be seen but a cicatrized patch in left macula lutea and atrophy of the optic papillæ; no nutrient vessels were to be seen in either optic disc. V. equals O. right, and simple perception of light left; pupils still dilated. I have heard that sight has not improved in this case since that date.

Do not the above cases furnish a sufficient answer to the question? Acute albuminuria, from whatever cause, is an exceedingly fatal affection when it has so impressed the system as to become manifest in and upon the retina. Of the truth of this I have had abundant evidence, as it has been my fortune to meet with at least thirty cases of retinitis albuminurica, a very large majority of them being in men between twenty-four and forty-eight years of age. Most of them have consulted me for dimness of vision, which they supposed could be remedied by glasses, never suspecting that any disease existed.

P. N. D——, aged twenty-nine, a mechanical draughtsman, called upon me, October 26, 1877, on account of dimness of vision, for which he desired me to examine him for glasses. His V. equaled $\frac{20}{200}$ right and $\frac{15}{200}$ left eye. Negative and positive glasses were placed alternately before each eye, but did not improve his sight in the least. The ophthalmoscope quickly pointed to the deposits and extravasations of blood in the fundus of each eye. "Have you had any trouble with your kidneys?" was asked of him. "No, I never had better health in my life, and I weigh twenty pounds more than I ever did," was his reply. His urine was found to be heavily laden with albumen, nearly all of it becoming coagulated under the application of heat and nitric acid. I advised him to consult one of our best physicians, but he seemed to think that I was unduly alarmed about his case. He subsequently called Dr. F. S. Newcomer, but soon had convulsions and died on November 25th, just one month after he called on me.

And so I could go on, repeating cases similar to this one. But two weeks ago a physician, for whom I had prescribed sphero-cylindrical lenses eighteen months before, called upon me for a change of glasses, as his served him no longer—could not see to read with them; but on looking into his eyes there sat the dread monster, as boldly prominent by the aid of the ophthalmoscope as Gibraltar's Rock to one in the Straits of the Mediterranean. I advised him not to change his glasses, but he persisted in having me order them; but in four days I received a despatch from his city, countermanding the order, and informing me of his death.

Some of my patients have improved temporarily under a milk diet and medicines; some have been benefited by going to mineral springs. One very fine-looking young man became disheartened at his increasing blindness and shot himself. But, so far as heard from, all but two have died inside of two years. Remember that I do not consider simple cases of albuminuria necessarily fatal; on the contrary, numbers recover and live for many years, but it is my experience that when it has so affected a patient as to become manifest in the retina but about one in ten live over two years; most of those which I have seen died inside of six months.

If, then, this disease is so frequently fatal to life, are we not justified in certain cases in recommending the induction of premature labor?

ON THE APPLICATION OF ALEXANDER'S OPERATION TO PROCIDENTIA UTERI; WITH REPORT OF TWO CASES.[1]

By ELIZABETH STOW BROWN, M.D.,

NEW YORK.

THE position of the uterus in the pelvis depends on the state of the cellular connections; the inclination of its axis upon the condition of its ligaments; its dimensions upon the functional state. Of the cellular connections, the most important is the subperitoneal pelvic connective tissue (containing elastic and smooth muscular fibres), particularly where it surrounds and accompanies the uterine blood-vessels. The latter portion is strengthened by additional trabecular filaments (Savage).

The utero-sacral ligaments are regarded by Aran as the only true ligaments of the uterus, their function being to hold the cervix to the posterior and upper part of the pelvis. Their relaxation and elongation cause the cervix to slip forward and downward. The round ligaments, passing backward through the inguinal canal, crossing in front of the spermatic artery, and going between the layers of the broad ligament to the anterior and superior part of the uterus, consist of fibro-cellular substance, muscular fibres, vessels, nerves, and absorbents. In the test of the strength of the round ligaments by Drs. Polk and Wright (THE MEDICAL RECORD, July 3, 1886), one broke at five pounds, having stretched to twice its length; the other was broken at four and three-fourths pounds. This was a strain far exceeding that demanded functionally of the ligaments. In the human subject the function of the round ligaments is generally agreed to be to prevent the fundus from being pressed too much backward; to aid in preventing the entire body from being prolapsed and resting with undue weight upon the rectum; and to facilitate the process of parturition by fixing and maintaining the uterus in due relation to the pelvis during the pains of labor.

Uterine prolapse is admitted to be the joint result of rupture of perineal structure, elongation of internal ligamentous supports, and stretching or forcible separation of the subperitoneal pelvic connective tissue. Of these deviations from the normal, the lengthening of the utero-sacral ligaments and the yielding of the connective tissue are the most essential.

The state of complete prolapse, as we see it, shows loss of perineum generally (but not invariably); prolapse of vaginal walls or inverted vagina; displacement downward and forward of the cervix from elongation of the utero-sacral ligaments; displacement backward and downward of the fundus. Dissection will show the blood-vessels leading to and from the uterus lengthened, straightened, and taking a new course; the ligaments, including the round, increased in length; the alar mesentery lengthened in its base line but otherwise in normal position.

What is the object in procidentia uteri in shortening the round ligaments, drawing the fundus up to the pubes, and placing the uterus in anteversion?

First: By maintaining the uterus in an elevated position in the pelvis, it is hoped to secure the retraction and consolidation of that subperitoneal pelvic connective tissue on which the position of the uterus so largely depends. That the maintenance of an elevated position in the pelvis by means of the round ligaments is not, however, the main or immediate expectation, will be shown later. Savage teaches us that if the connective tissue which has yielded to such an enormous extent, is relieved for a sufficient length of time from the weight of the prolapse, it will securely contract and consolidate.

Second: By putting the uterus in anteversion the current of the forces which gravitate toward the pelvis will converge behind the organ, instead of impinging upon its surface on top or in front. This does away with the pressure into retroversion, the first step in descent (Grailey Hewett).

Alexander never claimed that the round ligaments would hold up a prolapsed uterus when all its supports were gone, or so lax as to be practically useless. He but suggested that putting the uterus into forced anteversion takes away its wedge-like action; and, that when cervical supports are gone, we counterbalance the slipping forward of the cervix by bringing the fundus forward, maintaining the uterus at right angles to the vagina.

As preliminary operations, if the indications are present, a trachelorraphy, a colporrhaphy, or a perineorrhaphy may be done. Alexander has laid no stress on the latter operations taking precedence of the shortening of the round ligaments, though Doléris has done so. The advantages of their precedence, however, are obvious. Doléris, noting the behavior of the bladder where both ligaments are shortened, urges the drawing out of one ligament only. He says: "If there is cystocele, the shortening of the round ligaments, far from lessening it, actually increases it at first. Since the bladder cannot rise when distended, but must extend laterally, or downward as a subpubic pouch, it is impossible that this lateral distention of the bladder should not finish by exercising a traction upon the neck of the uterine body, with which this organ is so intimately connected. This traction eventually causes the uterus to redescend and reproduce the prolapse sooner or later." Though, of course, unless the round ligaments stretch, the uterus even then could not become procident. Doléris, having in mind this mechanism of the distention of the bladder, is convinced that it is better to shorten one ligament than both. He believes that the search for the second ligament has often helped to cause suppuration in the first wound. The other ligament can be shortened later, if one is found insufficient. Doléris also affirms that one ligament sufficiently sustains the uterus while it is deviated to one side of the bladder.

The after-treatment is not the least important part of Alexander's operation. It depends upon two limits of time. The first is the time required to unite the ligaments to the pillars of the ring, to the wound, and to the canal. This, according to Alexander, is about three weeks, and determines the period of decubitus. The second limit of time is that required for the secure contraction and consolidation of the connective tissue. Now, since the longer the uterus has been prolapsed, the longer it will take for the cellular tissue to return to its normal state, this period will be in direct proportion to the duration of that previous condition. It has been suggested, and with unquestionable propriety, that this return of the connective tissue to its normal state is practically a species of involution, and is the result of the alterations produced in the circulatory conditions consequent upon the new position of the uterus. In old cases of prolapse these changes will probably not take place in less than a year, if so soon. The length of this period of time should determine how long the patient should wear a pessary. The additional relief to the connective tissue afforded by the pessary is certainly desirable. The drawing of the fundus up to the pubes does not constitute the desired result; but that result is rather the return to the normal of the connective tissue surroundings. Hence we ought not to speak of the results in Alexander's operation in less than one year.

---

[1] Read before the Alumnæ Association of the Woman's Medical College of the New York Infirmary, October 17, 1887.

Patients must always be warned about constipation and straining efforts at stool, and against attempting to lift heavy weights; while especial caution must also be insisted upon in regard to conjugal relations, which should not be resumed under two months after the operation.

In comparison to the whole number of recorded cases, Alexander's operation has been done for procidentia but few times. There are on record several hundred cases, of which only about forty-six are for this condition. Recorded failures for procidentia are but three: one of Alexander's cases, where the ligaments stretched; one of Gardner's cases, where, he admits, the ligaments were not drawn out enough; and one of Campbell's, where the operation was imperfect from a previous peritonitis.

The two following cases may be added to those already on record.

Case I.—Mrs. S——, thirty-five years of age, married eight years, American. Has had four children. The second child was premature. The uterus first became prolapsed after this confinement, four years ago. During the last two pregnancies prolapse persisted in the latter months. The patient first came requesting immediate operation, as she feared pregnancy, having had menstruation delayed two weeks, and dreaded very much suffering as in previous gestations. She could not wear a pessary, principally because of the ruptured perineum. The operation was performed February 7, 1887. Both ligaments were found varicose. The right was small and weak, and as it was drawn out, about three inches, stretched perceptibly. The left ligament was large and strong, and was drawn out about four inches. It was then passed through the superficial fascia to the opposite side and tied in a knot with its fellow. Primary union occurred on the right side, but union by granulation on the left side. An inflated rubber ring was introduced into the vagina immediately after the operation. During the two weeks following, the patient at times complained of "dragging pains" in the wounds, but of nothing else. On the eleventh day the patient began to menstruate, anticipating her period by one week. She had considerable pain (which was not her habit), described as "cramps." After three days the flow became profuse, and was checked by ergot. On the fourteenth day the perineum was repaired and the patient spent two weeks more in bed. On getting up at the end of the four weeks, the pessary being still in place, the uterus was well held up to the pubes, and the cystocele, which before operation was very marked, was scarcely apparent. From this time up to about four months after the operation, however, the cystocele increased, and then receded until the present time, when it is very slight. Now, nine months after the operation, the uterus is quite firm in its position, the fundus well up to the pubes, the cervix back in the hollow of the sacrum. The patient feels very comfortable, and is in better health than for many years before. She still wears the pessary.

Case II.—Mrs. E——, forty-five years of age; married twenty-five years; German; has had five children. The procidentia has existed about twenty years. Passed the menopause about three years ago. The patient has been accustomed for years to return the uterus to position several times a day. I was called to her house to relieve her of a condition which was practically a strangulation of the uterus outside the vulva (suggested as possible by Grailey Hewett). After an unusual strain the uterus came down, but could not be returned as before. Soon acute pain set in. The patient was unable to sit, stand, or walk. Defecation and urination became extremely difficult and painful. The extruded organ swelled and became very sensitive. This state had continued for a week, the patient being obliged to remain in bed, before I saw her. Examination showed the perineum ruptured, the cervix outside the vulva, the vagina inverted, and the vulvar orifice tightly grasping the uterine body. The bilaterally fissured cervix was enormously œdematous and purple. Large true ulcerations existed on the segments of the cervix. The vagina was also purple and œdematous. The patient was placed in the genu-pectoral position, and by squeezing the lips of the cervix together while exerting considerable pressure in the axis of the pelvis, the uterus slipped up. Before operation, the ulcerations on the cervix had healed under treatment, and the uterus had been supported for four weeks by pads of cotton. The patient was unable to retain a pessary. On May 30, 1887, the operation was performed. The ligament was readily drawn out on the right side, but in this inguinal canal was found a loop of Fallopian tube. Following this down, the finger readily felt the ovary of that side. The tube was returned to the abdominal cavity with proper antisepsis. The canal of Nuck was very redundant on both sides, and the peritoneum was opened in both canals. The ligaments were both drawn out about four inches, brought through the superficial fascia to the median line, where they were sutured into an incision just above the pubes. An inflated rubber pessary was inserted before the patient left the table. Decubitus was maintained three weeks. There was no elevation of temperature at any time. Both wounds healed by primary union, and the patient never at any time complained of pain. The perineum was not restored. Now, five months after the operation, the condition of the case is not so satisfactory as that of Case I. I consider this as largely due to the omission to restore the perineum. The cystocele is quite marked, and the cervix is on the floor of the vagina; but the fundus is held closely up to the pubes. A large air-pessary is used, but on account of the loss of perineum is not well sustained. However, the patient expresses herself as exceedingly comfortable, and perfectly satisfied with the results of the operation.

A CASE OF INTESTINAL OBSTRUCTION CAUSED BY A DIVERTICULUM.

By FRANCIS P. WHITTLESEY, M.D.,

GREAT BARRINGTON, MASS.

Harry S——, aged two years. The patient had been a healthy child, with the exception of an illness toward the end of his first year. I am informed that at this time the symptoms were those of some abdominal disease, relief following a discharge of pus from the rectum, after which convalescence was prompt. The diagnosis of the attending physician was pelvic abscess rupturing into the intestine. The child enjoyed a year of health. On August 6, 1884, I was called to see him, and found him suffering from colicky pains, without abdominal tenderness and with moderate distention. He had vomited a banana, which he had eaten about two hours before the attack of colic. He received tr. opii camph. (a moderate dose sufficing to quiet pain) and a dose of castor-oil. Only a slight evacuation of the bowels followed the cathartic, and subsequent attempts to secure this result with rhubarb and magnesia, castor-oil and repeated enemata, failed. The child, however, did not appear very ill; he played with his toys, took a sufficient quantity of liquid nourishment, and required only moderate doses of bromide of sodium to allay restlessness at night. Pulse and temperature did not indicate any serious condition. There was no vomiting after the first day of his illness, and little abdominal distention. Gas was voided both by the mouth and per anum, and was noticed to have in both cases a very offensive and stercoraceous odor. He remained in this condition until 1 A.M. of August 9th, when I found him in collapse, with a cold, clammy sweat, and almost imperceptible and very rapid pulse, and very great distention of abdomen. After administering sherry wine and spts. ammon. aro., to which he responded, a final attempt was made to secure an evacuation of the bowels with an enema, castor-oil being used on the abdomen by inunction. The enema was voided without fecal matter, and the patient died at 6 A.M., five hours after the first appearance of collapse, and, I may say, of urgent symptoms.

Autopsy, made nine hours after death. Rigor mortis well marked, body well nourished. On opening abdomen, stomach and small intestines protruded, and were found enormously distended with gas. The large intestine was empty and collapsed. Beginning at the pylorus, the small intestine was examined and found in normal condition until a point about fourteen inches from the ileo-cæcal valve was reached. Here there was found a diverticulum springing from the ileum, about one inch in length and directed backward, which was by its extremity firmly attached to the posterior wall of the pelvis. A constricting band was thus formed, and beneath it were crowded about twelve inches of small intestine, and in so firm a manner that escape of the constricted intestine or passage of its contents was impossible. The gut at this point was of a dark-red color, slightly softened, and would soon have become gangrenous.

A POSSIBLE CARRIER OF INFECTION.

By D. LICHTY, M.D.,

ROCKFORD, ILL.

I have been reading the discussions on scarlet fever in the medical journals, and the series of letters in *Science*, and in support of the theory *de nihilo nihil fit*, I will offer a factor I have never seen alluded to in the literature on this subject.

In an active and extended experience of twelve years in country practice, where much of the produce that is consumed in cities originates, I have observed that it is the custom among the farmers, especially the younger families or beginners, to make butter in the house, in larger or smaller quantities; and in winter-time, to prevent the milk from freezing, it is usually kept in the kitchen, which is also the living-room, and often the only place in the house where a constant fire is kept. In this room the convalescents stay, and to it are often carried the sick, whatever may be the nature of their illness, whether diphtheria, scarlet fever, or what not, because it is probably the only room where an attempt at equable temperature would be successful. Here the milk from which butter is made is kept in large, shallow pans, sometimes on open, temporary shelving, but more frequently in "safes"—a light wood cupboard with wire gauze or perforated tin panels at the ends, and folding-doors of the same material. Now there is nothing in this to prevent the exhalations, desquamations, or disease-germs from being absorbed—and nothing possesses absorbent properties more than fresh milk—or impinging on the surface of the milk from which it, with the cream, is carefully skimmed until sufficient is gathered for churning, when it is made into butter, packed and carried to its home market, from thence to anywhere and everywhere, without ever having been subjected to any influences, either thermal or chemical, to destroy or impair organic life.

I have also seen the mother, who was the housekeeper and only nurse, leave a large wooden bowl full of butter, in which her hands and arms had been immersed nearly to the elbows, and follow me through two adjoining rooms, in which her children were sick with scarlet fever, give me the history of their illness the night previous, receive directions and instructions, and return to her butter-packing without stopping to wash her hands. And this butter was sought by local dealers, shipped to city markets, where well-watched and carefully isolated innocents developed those mysterious *de novo* cases of scarlet fever.

A CHEAP AND EFFECTIVE TEREBINTHINE BATH.

By HOWARD PINKNEY, M.D.,

NEW YORK.

The following is a simple device for making a very agreeable and effective terebinthine bath. This method of preparing a turpentine bath is probably well known to, and been used by many others, the process being so simple I presume they have not thought necessary to publish it. If it has been so published, I have not seen or heard of it. It only occurred to me during a recent and painful illness, and is as follows: I was being treated by my friend Professor J. R. Leaming; one portion of his treatment, upon which he particularly insisted, was that certain portions of my body (back and chest particularly) should be rubbed twice daily with a mixture of oil of turpentine and vaselin. These applications gave me great relief, nevertheless I cannot say I looked forward with pleasure to them, as almost every movement was painful. At this time the idea of replacing the rubbings by a turpentine bath occurred to me. But how to make the bath so that the oil should not float on the water, but be thoroughly and evenly mixed with it, was the question. I thought of the different methods that I had used turpentine in my practice. The mode of using it with soap, for rectal injections, seemed practicable for bath use. Thereupon I had my nurse make, in a large bottle, a saturated (six ounce) solution of "old yellow soap." When prepared, three or four ounces of oil of turpentine was added, and the contents well shaken. This formed a very nice, creamy-looking emulsion. I had my bath-tub filled with hot water, and half the emulsion added. I was then placed in the bath, which exhaled a very pleasant and distinctive pine odor. (The unpleasant and pungent vapors from the turpentine seem to be changed by emulsifying.) After remaining in the bath about five minutes, I experienced a decided feeling of relief from pain, and a genial glow over all the immersed portions of my body. After remaining fifteen minutes I was put in bed, when I soon felt a decided (not unpleasant) tingling or pricking sensation of my skin. In a short time I fell asleep, and when I awakened I was much freer from pain than at any time during my sickness. The baths were continued as occasion required, until my convalescence. Judging from the effects on my own person, I believe that they will prove especially useful in the following diseases, viz., rheumatism, gout, insomnia, laryngitis, bronchitis, and in the early stages of eruptive fevers. There is only one precaution that I know necessary to be taken in using turpentine locally, *i.e.*, to protect all, especially sensitive and denuded, parts by the application of some salve, as cocoa-butter, simple ointment, etc. These home-made terebinthine baths have the following to recommend them, viz.: They are equal, if not superior, to any of the pine extracts used for baths; they are much cheaper, costing only a few cents; they are cleanly, having an excess of soap; every physician will find at or near the house of his patient the materials for making, viz., water, soap, and turpentine.

A PECULIAR CASE.

By F. W. EDWARDS, M.D.,

WILMOT FLAT, N. H.

David M. C——, aged seventy-six, had been an invalid for at least eighteen months, and many physicians had treated him during that time. He presented a sallow and emaciated frame, the whites of the eyes were yellow, and the tongue was almost raw, and fissured deeply in every direction. He could make but little water at a time, but was forced to do so often; was constipated, and each movement consisted of a few balls of fæces, which came with the injection he was obliged to use; hands and feet always cold; abdominal organs sound, except stomach, which gives him much trouble. When a child of about twelve he injured himself in the region of the stomach, and vomited a quantity of blood, and he did not recover completely for some years. Now the stomach is intolerant to everything, except a mouthful or two of baked mashed potato, and all medication must, of necessity, be per rectum. Mind bright and cheerful, except when he has what his wife calls a "spell." At about four o'clock each afternoon he becomes cold all over, has a fluttering in the pit of his stomach, and then there is a feeling as though a veil was being drawn over his head, when he becomes stupid, and nearly or entirely loses consciousness. Invariably he would think it to be the day following, and when he desired to micturate or expectorate he would as soon use the corner of the sheet as the vessel or cuspidor. His eyesight was perfect, so far as recognizing friends was concerned, but otherwise he would see double, upside down, and, at times, a number of the same object, close together, looking, as he expressed it, like a file of soldiers. These spells would last from four to six hours, and during this time he had the appearance of an epileptic, but when they had passed off he was just as bright and cheerful as before. His feet, legs, arms, and hands would become very stiff and blue when the attacks began, and continue throughout. The physicians all treated him for "liver disease," but they all said they did not know what caused "the spells," and that he could not possibly live. I had three or four doctors in consultation, and some called it hystero-epilepsy, while others attributed the cause to the injury of years before, with possible perforation, etc. I was not satisfied with such diagnoses, and after treatment for two weeks or so the patient placed himself in my hands unreservedly. After a blunder or so I put him under treatment for malarial disorder, and after using four or five suppositories, containing iron and quinine (the latter in ten-grain doses), I was not very much surprised to see all bad feelings and spells disappear, and then, by the use of cod-liver emulsion, and maltine with pepsin and pancreatin, I soon had him on his feet and as well as he will ever be.

THE TREATMENT OF MEMBRANOUS CROUP WITH BICARBONATE OF SODA.

By CHARLES L. HOGEBOOM, M.D.,

JAMAICA, L. I.

A brief statement of the success which I have had in the treatment of membranous croup, or, as Dr. Flint preferred to call it, laryngitis with exudation, may perhaps be thought worthy of consideration. The idea occurred to me that we needed a therapeutical agent to act more promptly on the blood and on the assimilative action in the system, or at least the tissues in the region of the exudation. The viscous plasticity of the blood requires to be changed very soon in acute cases to avoid dangerous laryngeal obstruction, and it struck me that nothing is so well calculated to effect this as the introduction into the system of a sufficient quantity of the natural alkali of the body, soda, in the form of the bicarbonate. In the next case of membranous croup which I was called to attend, and which occurred some time in the year 1880 in the Eastern District of Brooklyn, the patient being a child aged about three years, I commenced with an eighty-grain dose of bicarbonate of soda dissolved in half a teacupful of water, to which a tablespoonful of milk was added to somewhat disguise the taste and insure deglutition. This was followed with a thirty-grain dose every hour until the laryngeal symptoms abated. Weak milk and water was also given at intervals, and warm fomentations applied to the throat. I used no other medicine in the treatment of that case, nor in a considerable number of other cases of simple membranous croup which occurred afterward.

I had always been in the habit of using bicarbonate of soda freely in various diseases, particularly in typhoid fever and in scarlatina, in connection with the usual tonics and other remedies, but had never before conceived the idea of employing it as a weapon to rival in power calomel and tartar emetic. To become convinced that it is more efficient in many forms of disease, I believe it is only necessary to use it in sufficient quantities. I will not occupy further space by going into any detail of the cases, merely remarking that I sometimes gave even larger doses, according to the age of the patient, than those above noted.

A CASE OF BELLADONNA-POISONING.

Dr. E. A. Chapman, of Belleville, N. J., writes: "On the morning of January 19th a message came to me from Miss S——, aged forty-two, saying that she was not sick but wanted me to call and see her. The call not being pressing, I did not reach her until I had visited several other patients, about 2 P.M. I found her very talkative, and somewhat delirious; pulse, 96; pupils large; unable to walk or stand long, and complaining of dryness of the throat, heaviness of the arms, and that she could not see well. In answering questions she would begin properly, but soon wander. I asked her what she had for dinner. She replied, 'Nothing but what was good, potatoes, beef, and *pins.*' On inquiry, I learned that the evening before she had removed from her chest all that remained of an old belladonna plaster, and applied a new one, and that the skin was abraded in places. There could be no doubt as to the diagnosis, so I caused the plaster to be removed and the part thoroughly washed. I gave her repeated doses of sulphate of morphine and bromide of potassium. The next day she was better, and soon entirely recovered."

UNUSUAL EFFECTS FROM SALOL.

Dr. Charles A. Church, of Bloomingdale, N. Y., writes: "I had occasion some weeks since to administer the new drug salol for its antiseptic properties in a case of typhoid fever. The patient was a young man, twenty-eight years of age, of fine physique, who previously to this attack of fever had always enjoyed excellent health.

"I prescribed five-grain doses every four hours, with good results, it lowering his temperature and relieving the tympanites, until the third day, when the nurse told me that the patient's body was broken out with a rash, which made him very restless. On examination I found an eruption, resembling that of herpes, covering the upper part of the trunk and extending as low as the tenth rib. The treatment consisted of a removal of the cause, and a local application of five grains of carbolic acid to an ounce of cosmaline. This application allayed the itching and caused the rash to entirely disappear in three or four days. I attributed the cause to an idiosyncrasy on the part of the patient against the salicylic acid contained in the salol. I would like to inquire if any other physician has had a similar experience."

Cholecystotomy.—At a recent meeting of the Medical Society of London (*The Lancet*) Mr. J. Knowsley Thornton read notes of two cases of cholecystotomy. The first, a female of forty-five, was placed under his care by Dr. George Johnson, and was operated upon when deeply jaundiced, and in very broken health from the pain of constant attacks of gall-stone colic. A single stone was found impacted in the common duct; the bladder and its duct being much contracted, rendered the operation very difficult, and it was found impossible to follow the usual practice, and suture the edge of the wound in the gall-bladder into the parietal incision. It was therefore carefully closed by four silk sutures and dropped into the peritoneum, glass drainage-tubes being placed in the peritoneum just below the liver and in the pouch of Douglas, through a counter-opening above the pubes. The patient made a good recovery, and remains well. The second case was that of a female, aged fifty-six. The operation was similar, one large stone being impacted in the cystic duct, which was contracted in front of it; and two other large stones were found impacted in the common duct. This patient also made a good recovery. The difference between such operations and those in which the gall-bladder is distended behind a stone impacted in the cystic duct were pointed out, and the precautions to be observed in each operation were discussed. The entire removal of the gall-bladder, and the possibility of forcing the stones through by manipulation without surgery, were mentioned, and some curious cases which had come under the author's notice were briefly referred to. Dr. George Johnson pointed out that in many cases of jaundice the history of a sudden onset with pain could not be relied on. He quoted a case in which a diagnosis of gall-stone having been made chiefly for this reason, operation revealed a scirrhus tumor at the end of the duct. A second case with similar history proved to be one of hepatic hydatid, in which secondary cysts were periodically passed by the gall-duct.

Progress of Medical Science.

Thallin in Gonorrhœa.—Dr. Goll, of Zurich, regards the salts of thallin, and especially the sulphate of thallin, as an effectual and but slightly irritating antidote to the gonococcus virus. He has also employed the tartrate of thallin in one and two per cent. solution in recent cases of gonorrhœa without waiting for the inflammatory stage to pass entirely. It appeared to act well, first changing the purulent secretion into one of a milky or slimy nature, which in turn disappeared. Still more active and beneficial was a two and two and a half per cent. solution, although in some cases this caused some inflammatory symptoms. In the chronic stage he employs a solution of from one to one and a half per cent. as an irrigation, with favorable results. Dr. Kreis, also of Zurich, was led by the observations of Schulz and Pisenti relating to the antiseptic nature of thallin to try its effects upon gonococcus cultures: (1) By bringing a solution of thallin into contact with flat cultures, and (2) by inoculating media containing thallin with gonorrhœal pus. In the first, two series of experiments were made, one with an acid and the other with a neutral solution. In all the trials no gonococci developed. In the second experiment the medium prepared with thallin solutions (neutral and acid) were inoculated with cultures of gonococci and placed in the hot-air chamber; the result was that no gonococci developed, while a control experiment at the same time carried out in a medium free from thallin showed, after twenty-four hours, commencing development of typical gonococci. The strength of the thallin solutions used was from one-half to four per cent.—*Journal of Cutaneous and Genito-Urinary Diseases*, February, 1888.

Puerperal Relaxation of the Pelvic Ligaments.—Dr. Driver, of Cambridge, Mass., concludes, from his observation of three hundred cases of parturtition, that: (1) The presence of relaxation depends very much upon the strength of the bony and ligamentous structures of the skeleton—that is, it is more apt to occur in the woman of poor physique. (2) That age does not determine its presence, at least the degree of it. The age of observed cases ranges from fifteen to forty-four. (3) It is not constant, but a degree of it is natural at time of labor, and may exist during pregnancy, and even in the early months. (4) There may be great motion and no lameness or impairment of walking power. (5) There may be a general degree of motion and great lameness. (6) Lameness depends upon pathological conditions of the junctions, pubic and sacro-iliac. (7) Pain at the sacro-iliac junction of one side proves that on that side is the pivotal motion of the ilium on the sacrum. It may occur in non-puerperal females, in sterile, and virgins. (8) Patients may recover from a most serious condition of lameness without treatment. (9) The most careful treatment, with all the aids that wealth can bring, may not restore firmness to the pelvis. (10) Many a case of lingering disability after confinement may have been due to this cause, and it is well, when you cannot find out "what is the matter," to test the condition of the pelvic ligaments. (11) A small degree of relaxation on separation may facilitate delivery, and may be a factor that saves the use of forceps. The treatment most successful was an abdominal bandage of twilled cotton, five inches wide, with padded perineal bands one inch wide. In some cases cold bathing and massage were added.—*Boston Medical and Surgical Journal.*

Myositis Syphilitica.—At a recent meeting of the Society of Physicians of Vienna, Professor Neumann read a paper on myositis syphilitica. He first mentioned the investigations of others on syphilitic myositis, such as those of E. Wagner, Rokitansky, Virchow, Ziegler, Tschainsky, Spina, etc., and then described his own clinical experience of syphilitic disease of the extensor carpi radialis, the extensor digitorum communis, the temporalis muscle, the trapezius, and especially the sphincter ani externus. When all trace of syphilitic disease of the mucous membrane of the rectum had disappeared, severe pain was often complained of in the region of the anus. It consisted in powerful contractions of the sphincter ani externus (tenesmus), which were the result of a syphilitic inflammation of the muscle. In syphilitic myositis, the blood-vessels of the perimysium which covered the fibres of the muscles were chiefly the point of departure of the infiltration. In the perimysium itself, as well as in the spaces between the fibres of the muscles, many serpentine blood-vessels were to be found, which were filled with blood to a high degree, and surrounded by granulation cells. The connective tissue was proliferated abundantly. The nuclei of the muscle fibres of the inner surface of the sarcolemma also proliferated, and could be distinctly recognized, owing to their arrangement like a string of pearls of from five to twelve nuclei lying close to each other. In slight inflammations of the muscles, this increase of the muscular nuclei could persist, according to the opinion of Recklinghausen. In a later stage of the disease the granulation cells increased in the interstitial connective tissue, whereas the muscular substance disappeared more and more, and finally, when the process was completed, were replaced by fresh connective tissue. Such proliferation had also been observed by Erb, Hay, Heidelberg, and Kraske in rabbits and guinea-pigs, in muscles which had become paralyzed as a consequence of neurotomy. In three cases in which Professor Neumann had sphincterotomy performed by his assistant, Dr. Ehrmann, for the relief of permanent and severe pains, the above-mentioned conditions were also found to be present. According to the experience of Professor Neumann, the sphincter ani externus was the muscle which became in most cases affected with syphilitic myositis. In the course of six years, acute syphilitic myositis of the other muscles had been observed, at the clinic of Professor Neumann, on three patients, whereas in the spincter ani externus it had been seen five times in two years. This did not include cases of gummatous degeneration of the anus. It was also remarkable that the disease in question chiefly affected women, which might be explained by the frequent occurrence in them of papulæ and rhagades about the anus; this was also partly due to the fact that syphilis in women was attended by discharge from the vaginal mucous membrane, which trickled to the anus and irritated the parts, giving rise to an inflammatory process.

MÉNIÈRE'S DISEASE.—Dr. Gellé, from recent researches on Ménière's disease, has arrived at the following conclusions: Typical vertigo, characterized by serious attacks, may exist for years without the presence of any lesion in the auditory nerve. Vertigo is observed in various lesions of the middle ear. These tympanic lesions all tend to close up the labyrinth by one of the following processes: the stapes becomes attached to, or permanently fixed in, the fenestra ovalis; or the fenestra rotunda is obliterated. Every movement communicated to the labyrinth produces an injurious shock owing to the absence of any safety-valve. The mobility of a portion of the wall of the labyrinth is necessary to produce abnormal irritation in the auditory nerves. The state of hyperæsthesia and reflex hyperexcitability of the auditory nerve, resulting from repeated local irritation and functional excitation (deglutition, spasm of accommodation), is a most important element in the causation of auditory vertigo. The lesions and the pathogenesis of Ménière's disease are identical whether it be accompanied by tabes or not. The sense of hearing is preserved to a certain degree. This fact would justify the conclusion arrived at by Marie and Walton, in their investigations on vertigo in tabes, namely, that the auditory nerve remains intact in this affection.—*The British Medical Journal*, December 24, 1887.

CAUSES OF HYPERTROPHY OF THE SKULL IN RICKETS, MOLLITIES OSSIUM, OSTEITIS DEFORMANS, AND CONGENITAL SYPHILIS.—At a recent meeting of the Royal Medical and Chirurgical Society (*The Lancet*, December 17, 1887), Mr. W. Arbuthnot Lane read a paper on the "Factors that determine the Hypertrophy of the Skull in Mollities Ossium, Osteitis Deformans, Rickets, and Hereditary Syphilis." The author called attention to the desirability of separating the direct from the indirect effects of morbid conditions or diseases, especially in the case of those above enumerated. He referred to papers in the *Journal of Anatomy and Physiology* and in the "Guy's Hospital Reports," for 1887, in which he had explained the mechanical factors that determine the character of the deformities of the bones of the lower extremities in mollities ossium, rickets, and osteitis deformans. He had shown that these deformities are preceded and produced by a yielding of the sacrum in such a way that the lumbo-sacral articulation is displaced forward and downward from its normal relationship to the iliac bones and hip-joints. This alteration in the position of a joint through which the whole superjacent weight of the head, trunk, and upper extremities is transmitted from that normally occupied by it, necessitates, when the erect posture is assumed, that the hip- and knee-joints be flexed, and a consequent tendency for the long bones of the leg to yield in a vertical antero-posterior plane. He had also demonstrated the factors that determine the yielding of these long bones in a vertical transverse plane. He obtained his first clue to the conclusions at which he had arrived from a study of the changes that the skeleton undergoes in old age, and of the laws governing them. He attempted to prove that the factors that determine the thickening of the skull in mollities ossium, congenital syphilis, rickets, and osteitis deformans are purely mechanical, and that the hypertrophy is not the direct product of the morbid condition or disease, but a vigorous attempt, and sometimes the only attempt, on the part of the organism to retain its most important organ as free from the direct result of the disease as possible. He referred to a paper in the Transactions of the Pathological Society, 1884, in which he had disputed Rindfleisch's theory of the processes which ensue in the skull in mollities ossium, and detailed the arguments by which he arrived at his conclusions—namely, that in mollities ossium the thickening of the skull is dependent upon an endosteal, and later upon a periosteal, deposit of decalcified lamellæ of fibrous tissue, this being not a direct product of the condition, but an effort on the part of the organism to oppose and limit the baneful influence of the process of decalcification in so far as it affects the cranial vault. He applied the same arguments to the analogous condition of the skull present in osteitis deformans, rickets, and congenital syphilis, with the object of showing that in them also the thickening of the skull was (in a similar manner) a process of repair and not a direct result of the disease.

PERSONAL NOMENCLATURE.—In a letter on this subject to the Buffalo *Medical and Surgical Journal*, Dr. J. F. Baldwin gives the following interesting facts: "In the article on 'Nomenclature, Personal,' in 'Wood's Reference Handbook of the Medical Sciences,' occur definitions of these several operations. As the writer of that article, I may say that these definitions cost me more correspondence than all the other five hundred put together. The definitions of Battey's and Tait's operations are quoted verbatim from letters received from each operator. *Battey's operation*—'The complete extirpation of both ovaries, while yet in a state of functional activity, for the effectual remedy of cases of disease otherwise incurable.' *Hegar's operation*—The same as Battey's operation. *Hegar-Tait operation*—A misnomer of Tait's operation. *Tait's operation*—'Removal of the uterine appendages for physical disease other than cystoma: As the removal of the ovaries and tubes for uterine myoma; the removal of a tube for pyosalpinx, or other disease; or the removal of both ovaries and tubes for chronic inflammatory disease and adhesions.'"

THE MEDICAL RECORD:

A Weekly Journal of Medicine and Surgery.

WM. WOOD & Co., Nos 56 and 58 Lafayette Place

New York, March 3, 1888.

THE CLASSIFICATION AND TREATMENT OF THE INFANTILE DIARRHŒAS.

Too much attention has perhaps been paid to the question of the general treatment of diarrhœa of young children, and not enough to the differentiation of the various types. The forms of diarrhœa given by Henoch are cholera infantum, catarrhal diarrhœa, and dysentery. Other writers describe simple, bilious, choleraic, inflammatory, lienteric, and dysteric forms. Thus fine classifications either are not made, or great stress is not laid upon them practically. It is, at any rate, a frequent habit to prescribe about the same class of remedies for diarrhœas of nearly all forms, aside, of course, from dysentery. Dr. A. Lesage, in a series of articles upon "Dyspepsia and the Green Diarrhœa of Infants," in the *Revue de Médecine*, December, 1887, and January, 1888, calls attention to the importance of making sharper distinctions in the treatment of infantile diarrhœas. He makes the following classification: 1. Acute diarrhœa, alimentary or infectious. Of this form there are two types: (*a*) one in which the stools are yellow, small in amount, and containing much undigested food. Here a purgative is always indicated. (*b*) Acute infectious diarrhœa. Here the stools are numerous, yellow in color, neutral or acid in reaction, often fetid, and containing large numbers of microbes, which play an important part in the pathogeny of the trouble. Such diarrhœas often occur at the time of weaning, and in infants who are using the nursing-bottle. The methods of treating this form are two: First, to employ at once intestinal antiseptics, or, second, to give first a purgative, and then follow it with antiseptics, if needed. The best antiseptic in these cases, according to Lesage, is lactic acid, which should be given every quarter or half hour, or every hour, according to the frequency of the stools. It should be repeated for a day after the diarrhœa has stopped.

If purgatives are given, the choice should lie between castor-oil; calcined magnesia, gr. xv. to xlv.; or calomel, gr. iij. to gr. iv., for a child of two years, daily. After the purgation, if the diarrhœa has not stopped, astringents, opiates, or antiseptics may be given. Paregoric is thought to be the best form of opiate, while among astringents rhatany is given in the first place (gr. x. to gr. xv. every two hours). Weiss recommends the use of raw meat or powdered meat.

Discussing the subject of antiseptics again, our author says that we can lay aside resorcine, thymol, benzoate of soda, iodoform, and salicylate of bismuth, as having been proved inefficacious in his own and others' hands. The antiseptics which do give some results are naphthaline, used for infantile diarrhœas by Baginsky, Comby, Crämer, Winslow, Holt, and others. This drug is sometimes impure. The daily dose is from gr. vij. to gr. xv. Creosote, in daily doses of gtt. iv., has been recommended by Henoch. Beta-naphthol, so highly indorsed by Bouchard, has not yet been put to practical trial. Lactic acid is preferable to all the foregoing antiseptics, says our author.

The second form of diarrhœa is the *lienteric.* In this the stools are white at first, and of some consistence. Later they become liquid, but are still white, though occasionally and temporarily green with bile. In this form astringents, opiates, and alkalies do no good. The trouble lies in an alteration of the secretion of the pancreas, and perhaps of the liver. The milk, coagulated in the stomach, is not transformed into peptones by the pancreatic juice. The indication is to give pancreatine or trypsin, and this, says Lesage, is the only remedy that does any good, except, perhaps, a purgative, which may be given for the purpose of clearing out the fermenting undigested milk. At the beginning this alone may be sufficient; later, it is liable to fail.

The third form is the *reflex diarrhœa, à frigore* or from dentition. In these cases the stools are serous, yellow, and do not contain particles of the food. Opiates, rhatany, and lactic acid are the best drugs. If there is fever, aconite or antipyrin may be given.

The fourth form is the *green* or *bilious diarrhœa.* The stools are green and very acid. Bile is present in abundance, and the diarrhœa may be termed "polycholic." This type often occurs in the first month; it is apyretic and not accompanied, usually, with dyspepsia. It sometimes runs a short course, but not always, and it should always be treated. Purgatives do no good. Alkalies should be administered in doses of gr. xv. of bicarbonate of soda per kilogramme of infant. But the dose should not exceed ʒ j. gr. xv. This treatment is not always successful, however, and sometimes opiates and astringents must be added. If there is dyspepsia or fever, lactic acid or calomel should be given.

The *fifth form* is a comparatively new one. It is called by Lesage the *green bacillary diarrhœa.* The stools, though green, are not made so by bile, but by the action of a specific bacillus. They are but slightly acid, and give no biliary reaction. Fever is often present. Bacillary diarrhœa is rare before the first month, and it often occurs in epidemics. Lactic acid is an antiseptic for this, as it is for the infectious diarrhœa.

M. Lesage's lactic-acid medication has been favorably reported upon by MM. Hagan and Sevestre. The dosage is ʒ j. of a two per cent. solution, fifteen to twenty times daily.

STROPHANTHUS.

THE position of strophanthus as a therapeutic agent is still somewhat unsettled. It continues to be used, and favorable results are heard from it; but it has certainly not superseded digitalis, and has not gained a reputation equal to that of its older rival.

In a discussion on the subject of the action of strophanthus at the Berlin Society of Internal Medicine, January 9th and 16th, some interesting facts were brought out. Dr. A. Fränkel reviewed the history of the drug, describing the results obtained by Langgaard, Pins, Zerner and Loew, Hochhaus, and others.

It appears that the views of Fraser as to the physiological action of strophanthus have not been entirely confirmed. Some experimenters have found that its action on the heart as a stimulant was slight and tardy, and they have claimed that it was a heart-tonic indirectly only, through its power of relaxing the blood-vessels. Boyd and Langgaard (*Therapeut. Monats.*, August, 1887) found that in large doses it had a sedative action on the brain and spinal cord.

Dr. Hermann Haas, of Prague, made some interesting physiological observations (*Intern. klin. Rundschau*, No. 44, 1887) regarding the effects of strophanthus. He gave it to twenty young patients, and noted its effect on the heart-beat, blood-pressure, etc. He found that in afebrile patients thirty drops produced an impression in five hours; in febrile cases fifty drops were necessary. The results were a slowing of the pulse and loss of the visible cardiac impulse, which became diffused. The heart-action seemed quieter, and this effect lasted for four to five days. Haas thinks that strophanthus quiets the heart-muscle, and that its apparent tonic effect is due to the relaxation of the arterial walls and lessening of obstruction to the flow of blood.

Dr. Langgaard states that there are eighteen kinds of strophanthus on the market, from various parts of Eastern and Western Africa, and that these differ in appearance and medicinal character.

Among clinical observers of the effects of strophanthus, Pins seems to be most enthusiastic (*Therapeut. Monats.*, June and July, 1887). He finds it superior to digitalis as a heart-tonic, a reliever of dyspnœa, and a diuretic.

Fränkel himself is not so confident. He used strophanthus in twenty-two cases of cardiac disease. He found it most efficient in so-called functional disturbances of the heart, from excessive use of alcohol, tobacco, etc. It acted well sometimes in dropsical conditions; but it was never found to relieve dyspnœa, except indirectly, by relieving dropsy.

Dr. Paul Guttman reported the results of his experience in about forty cases. He was especially impressed with the diuretic effect of the drug, though it was not uniform in its action in this respect. It acted as a heart-tonic in some cases, but was not so trustworthy as digitalis.

Dr. Langgaard reiterated his views, in the discussion, viz., that strophanthus was not a direct heart-tonic, but rather a vaso-motor depressor.

Dr. Fürbringer had treated one hundred and twenty cases with strophanthus. Of these there were only thirty who had responded well to it, and of whom it could be said that the drug's action was permanently beneficial. He found, as had Dujardin-Beaumetz, that it was of no value in purely renal dropsy, and that in Bright's disease the drug is really not indicated at all. The indications for the drug were very difficult to determine. Several times Dr. Fürbringer had thought he could lay them down, but had been disappointed. The earlier the cases the better the action, as is the case with the other heart-tonics. Dr. Fürbringer believed that the chief action of the drug was on the heart, and that its dilating effect on the vessels was secondary.

It is apparent, from the contradictory reports so far furnished, that it will be necessary to get the active principle of the drug, and carefully test this before certainty can be reached regarding it.

THE TOBACCO HABIT.

"In every land and in every clime where the use of tobacco prevails it causes degeneration, degradation, debasement—physical, mental, and moral—disease, and death, or individual and national decadence."

Such is the statement of Dr. George J. Ziegler in an article on "The Tobacco Poison" in the *Sanitarian*.

"I do not believe there is any more harm in smoking a cigar or pipe, after eating, than there is in drinking tea and coffee. Any luxury carried to excess carries with it a penalty. For my own part, I consider that smoking acts as a sedative and equalizer of the temper, assists digestion, and is a medium of sociability among men which should not be discarded."

So says Dr. A. E. Adams, of Danbury, Conn., in an article entitled "Is Smoking Injurious?"

The doctors disagree, but there can be no doubt as to whose view is nearer the truth. The broad statement of Dr. Ziegler is contradicted not only by general experience, but by the undoubted fact that such countries as Germany and the United States, two nations which are certainly not suffering from decadence, consume three or four times more tobacco per capita than do the Spaniards or Italians, nations of by no means so vigorous a vitality.

The real facts as to the influence of tobacco on the health are fairly well established, and the occasional outburst of anti-tobacco fanaticism does not affect received medical opinion. Tobacco is pernicious to growing children. Used in moderation, the majority of healthy adults can smoke it without harm. It does not in these shorten life or produce degenerative changes. Nearly one-half of Professor Humphrey's collection of centenarians were tobacco-users. It is particularly harmless to those who live out-doors and engage in physical work. It is particularly apt to injure those who live in-doors. The worst feature about its use is the difficulty some persons have in smoking in moderation. This is especially true of brain-workers, and it is for this reason that physicians never advise the acquirement of the tobacco habit. But among the great mass of working-people the use of tobacco is apparently a harmless one.

A NEW NATIONAL BUREAU.

The agricultural element of this country has long striven for cabinet representation. It has been thus far compelled to content itself with a commissionership. Even that has not been granted to an interest of very great importance, namely, that of securing foods free from all adulteration. Recent revelations concerning this latter grievance seem to demand some attention from the general government. It is really a serious question as to whether the time has not come for Congress to take some definite stand upon the matter. In a word, the production of food-stuffs and their various preparations should be under national supervision.

It would be the height of folly to bring such a project under the supervision of a cabinet officer. That would mean politics, and we are cursed with too much of that already. A proper expert should be in absolute control, as in the case of the food-fish interest. We already have tea-inspectors under the direction of the Treasury Department, but their work is not done in a satisfactory manner. Witness the large amount of the article condemned by local health boards after it has been officially pronounced good. Plainly, the present methods of food examination are not what they should be.

We do not desire to be alarmists, but food-adulteration has been carried to such proportions that the scriptural suggestion of asking for bread and receiving a stone has become almost literally true. One of the recent numbers of the *Westminster Review* contains the following satire from the pen of a German: "There were four flies, and, as it happened, they were hungry one fine morning. The first settled upon a sausage of singularly appetizing appearance and made a hearty meal, but he speedily died of intestinal inflammation, for the sausage was adulterated with aniline. The second fly breakfasted upon flour, and forthwith succumbed to contraction of the stomach, owing to the inordinate quantity of alum with which the flour had been adulterated. The third fly was slaking his thirst with the contents of the milk-jug, when violent cramps suddenly convulsed his frame, and he soon gave up the ghost, a victim to chalk-adulteration. Seeing this, the fourth fly, muttering to himself, 'The sooner it's over, the sooner to sleep,' alighted upon a moistened sheet of paper exhibiting the counterfeit presentment of a death's-head and the inscription, 'Fly-poison,' and fearlessly applying the tip of his proboscis to this device, the fourth fly drank to his heart's content, growing more vigorous and cheerful at every mouthful, although expectant of his end. But he did *not* die. On the contrary, he throve and waxed fat. You see, even the fly-poison was adulterated."

The first question to be decided is, Have we the means in our present governmental system to carry out the end, or do we need new agencies? We have already alluded to the unsatisfactory work of the tea-inspectors. The plan has been suggested of placing the present internal-revenue inspectors in charge, in case the present Congress shall free them from their present duties by taking the tax off whiskey and tobacco. This is mentioned only to be condemned. In the first place, it is extremely unlikely that such a measure as the latter will be enacted in the immediate future. Secondly, the men now in office would have no technical knowledge of their new duties; and lastly, the service would still be, as it is now, under the control of the politicians.

While various State regulations are now in force, their power for good is almost nullified on account of the lack of such or similar regulations in adjoining States. Our vast internal commerce necessitates making this question a national one. A Bureau of Adulterations has been suggested by some, and fifty thousand dollars named as the amount to be expended the first year for its maintenance. The establishment of such a bureau will meet with resistance, perhaps, from dishonest manufacturers and tradesmen. An unorganized mutual-aid idea will show itself among them, as it has done with the milkmen, where, as as has been said, "one holds the can while the other pumps." But we believe that most of the retail dealers are honest, and are imposed upon by the manufacturers. Hence, any measure will be unavailing which does not go back to the fountain-head.

HOSPITAL PHYSICIANS AND GOVERNING BOARDS.

A CASE occurred in London recently in which the legal relation of the visiting physician, or surgeon, to the hospital management was brought up—and settled. A member of the surgical staff of the Queen's Jubilee Hospital was dismissed by the Governing Board, on the ground that he had accepted a similar position in another hospital where homœopathic treatment was allowed.

The dismissed surgeon, Mr. Millican, brought action in order to have himself reinstated. The Court ruled, however, that the Board had the right of dismissal. The visiting surgeon receives an honorary appointment, which is not in the nature of a contract. The relation is a "personal one." He had a license to use, but not an interest in, the property. He could, therefore, be discharged.

Put in plain language, it means that the visiting physician, or surgeon, is really an employé of the hospital officials.

PROHIBITING THE SALE OF SECRET MEDICINES.

A BILL which practically prohibits the sale of secret medicines has been introduced into the Assembly of the State of New York by Mr. J. W. Smith. It provides that no person or firm shall sell any medicinal preparation without first filing the formula of the preparation with the State Board of Health and receiving a license or certificate from that body.

It further provides that no so-called secret or proprietary medicine shall be sold, unless there is a printed formula showing the nature of the compound on the bottle, and also the words, "Sale authorized by New York State Board of Health."

It seems a very simple and manifest proposition that the public should be protected against the enormous swindling of the patent-medicine trade. And such a bill as the above would certainly promote the public good. But we fear that vested interests will prove too strong for it. The propriety of a printed indorsement by the State Board of Health might be questioned, in any event.

GOOD SOMETIMES COMES OUT OF LIQUOR.— A bequest has been made by a wealthy English brewer of $1,000,000 for the advancement of economic and sanitary science.

A DONDERS MEMORIAL FUND.—A joint committee has been organized by the London Ophthalmological and Physiological Societies, with the view of co-operating with the committee formed in the Netherlands to celebrate the seventieth birthday of the eminent professor of Utrecht, on May 27th next. On that date the law requires Dr. Donders' resignation as Professor at the University and Director of the Physiological Laboratory. It is proposed to raise a Donders Memorial Fund, to be devoted to some scientific purpose.

News of the Week.

The Ohio State Sanitary Association held its annual session at Toledo, February 9 and 10, 1888, Professor E. T. Nelson, Ph.D., President, R. Harvey Reed, M.D., Secretary. The first paper read was one by Mr. D. L. Stine, of Toledo, on "Sanitation in Architecture." The chief thing considered in this paper was the disposal of the soil and wastes of the home without offence to the occupants or their neighbors. "Cremation as a Sanitary and Economic Measure" was the next paper, by Dr. Lew Susser, of Canton, O. He thought complete combustion and consequent annihilation the only method by which the micro-organisms can be destroyed. Persons who have died from small-pox have lain in the ground for thirty years, and then, when the bodies were disturbed, they became the means of producing a local epidemic. The only objections to cremation are sentimental, but we certainly should not prefer corruption and putrefaction in the place of purification by cremation. "Ashes to ashes" is the appropriate finale of humanity. Most of the friends of incineration belong to the medical profession. The movement has been indorsed as a sanitary necessity by the American Public Health Association, the American Medical Association, and the Society of Medical Jurisprudence and State Medicine of New York. A number of gentlemen took part in the discussion, all favoring cremation. "The Effects of the Present System of Educational Methods on the Health of Women" was the subject of a paper by Dr. C. A. L. Reed, of Cincinnati. He drew a pen picture of the course of the young girl through school and the ruin of her health. He estimated that more than two thousand five hundred school-children in Ohio die annually of causes emanating from the school-room. He dwelt on school hygiene, particularly that with reference to female pupils and teachers. He recommended, as a remedy for the terrible destruction of health, that the custom of Germany be imitated, and facilities for physical culture be established at each school-house. Dr. A. Hult, of Waverly, read a paper on "Village Boards of Health." He urged their necessity, and recommended such changes in the law as would give to each incorporate village a health organization. Dr. George A. Collamore, of Toledo, read a paper on the "Duty of the Public to Sanitary Science." Dr. Wm. Owens, of Cincinnati, then presented a communication on "House Drainage and Sewer Connections." He thought no house having average sewer connections could be completely protected against sewer-gas. He proposed to correct this by establishing a ventilator between the sewer and traps on the soil-pipes, thus allowing the gas to escape into the open air. Dr. John McCurdy, of Youngstown, read a paper on the "Ventilation of Sewers." Dr. Victor C. Vaughn, of Ann Arbor, discussed the question of "Foods and Food Adulteration," in which he treated of the preparation of the various kinds of foods and the adulteration of the same. Dr. E. T. Nelson, of Delaware, made the presidential address, in which he reviewed the progress of sanitary science, and compared the present with the past condition of Toledo as an example. He described Hygeia, the city of health, the city of the millennium. Dr. R. Harvey Reed, Secretary of the Association, read a paper on "Passenger Coaches, How they should be Heated and Ventilated." He considered the prime factors to be efficiency, safety, simplicity, durability, and economy. He recommended pipes to carry heat about the sides of the car, also pipes to supply fresh air, and others to remove the cold foul air from the bottom of the car, and thus dispense with ventilators at the top and the opening of windows. Professor Search, of the Sidney public schools, read a paper on "Pure Air within Doors, and How to Obtain it." He thought there was certainly no reason why we should not have pure air. It is abundant, inexpensive, and easily attained; there is no excuse whatever for the lamentable ignorance which deprives us of that great necessity of life. Dr. Isaac D. Smead, of Toledo, discussed the question of "How far the Science of Ventilation has Advanced," and seemed satisfied that it was taking its share in the progress of the nineteenth century. "Cholera, its Prevention and Limitation," by Dr. D. H. Beckwith, of Cleveland, was the next subject on the programme. He discussed the problem of quarantine, and traced the spread of several epidemics throughout this country. He considered dread to be a potent factor in the dissemination of the terrible disease. Dr. Daniel Segur, of Toledo, made a report on Toledo's water-supply. Dr. J. A. Chesney, of Bucyrus, read a paper on "Meat-poisoning." The subject of trichinæ spiralis received merited attention, and several cases of the disease were cited. "The Duty of the Public to Sanitary Science" was the subject selected by Professor John Simpson, Ph.D., of Mansfield, O. The following officers were elected: President, Dr. G. C. Ashmun, of Cleveland; Vice-Presidents, Dr. John McCurdy, of Youngstown; Professor Ortau, of Columbus; Dr. S. S. Thorne, of Toledo; Secretary, Dr. R. Harvey Reed, of Mansfield; Treasurer, Dr. D. H. Beckwith, of Cleveland. Canton was chosen as the place for the next meeting, which will be held on the third Thursday in November.

The Proposed Asylum for Narcotic Habitués.—In our issue of December 31st last, editorial reference was made to a suggested asylum for the treatment of those addicted to the use of opium, chloral, and cocaine. We are pleased to note that a movement for opening such an institution in Brooklyn is now under way, and that a number of well-known gentlemen—whose names are elsewhere given—have expressed their approval of the work and their willingness to act as directors. There is no institution of this kind in the world, and it is quite fitting that in America, where, it is safe to say, narcotic habitués outnumber those of any other nation, there should be a remedial retreat for release from the enslaving power of these drugs. We cordially commend this project to the profession and the public, and bespeak for it a large measure of sympathy and financial support. A permanent fund of $200,000 is desired; the income from which, and from paying patients, will, it is thought, insure a financial success. Subscriptions, conditional on securing the entire endowment, are solicited, and may be sent to General C. T. Christensen, care of Drexel, Morgan & Co., New York.

The New Bacteriological Institute of Pasteur will be remarkable in many ways. It is to be of great extent, occupying over ten thousand square yards. Two principal pavilions will contain the laboratories, the amphitheatres, and consulting rooms. There will be no hospital, for, we are told, the institute "is not a *maison de santé*, but a school." On each side, uniting the pavilions, will be stables, fowl-houses, kennels, and rabbit-hutches for all the animals required for the various researches, which will not be confined to rabies, but will embrace all contagious diseases. Only one department will be devoted to rabies, at the head of which will be M. Grancher, who is styled "Apostle of the Religion of which M. Pasteur is the Prophet." The second department will be devoted to *inoculations charbonneuses*, swine measles, and calf-vaccination, the director being M. Chamberland. The third will be entirely private, devoted to researches in bacteriology, under M. Dudaux; and the fourth to medical bacteriology, under M. Roux. The building is calculated to cost two hundred thousand dollars, and the remainder of the funds subscribed will endow the institute, when opened next June, with about six thousand dollars a year. Yet it is denied that inoculations for rabies or charbon are of any value! The denials, fortunately for the institute, come chiefly from Germany.

A New Form of Infectious Pneumonia.—At the recent Medical Congress in Italy Professor Cantani presented a communication on a new form of infectious pneumonia which had been observed by him. The clinical history showed bronche-pneumonia, which had been preceded by a diffuse bronchitis, with remittent and very pronounced fever, considerable emaciation, and great enlargement of the spleen. The disease was contagious, and was a primary affection of the bronchi, which extended downward through the lung, and sometimes over the pleura and upward along the trachea, and even to the larynx and pharynx. Bacteriological examination revealed the presence of numerous diplococci, and especially streptococci, similar to those found in erysipelas. The pure cultures did not, however, produce erysipelas when injected subcutaneously. When they were injected under the skin of a rabbit's ear, only swelling and reddening at the site of puncture were produced. All the cases ran a favorable course.—*British Medical Journal.*

The Annual Death-rate in England, in 1887, was 18.8 per 1,000, being the lowest rate as yet recorded.

The Patient from Whom a Cerebral Tumor was Removed by Dr. Weir is not dead, as reported. We are glad to state that he is in good general health, able to go about freely, and is, as regards cerebral symptoms, better than he was before the operation, which was done more than three months ago.

Dr. Sharlau desires us to say that he advocates lateral decubitus in certain cases of transverse presentation and not the contrary, as reported in our recent issue.

A Nut for Inebriate Specialists to Crack.—Dr. C. Roberts, writing in the *British Medical Journal* on alcoholism, says: "Indeed, I think it is a great error to speak of the various conditions of the digestive and nervous systems resulting from the excessive or injudicious use of alcohol as a specific disease, as they are similar to those which result from the excessive use of other foods, nervous excitement, and mental and physical excesses of all kinds. The setting apart of the treatment of these diseases as a specialty is one of the greatest evils of the prevailing evil of specialisms, as is obvious by the nonsense which is talked by such specialists as to the hereditary character of the disease, and the incurability of some cases. At present we have no evidence that acquired habits are transmissible from parent to child, and, moreover, there are no definite and uniform lesions resulting from the use of alcohol to be transmitted, if such transmission were possible. That the child of a drunken mother should have feeble health is likely enough, as its nutrition has been interfered with; and that the children of intemperate parents should acquire their habits from imitation and the facilities for falling into them is likely enough also. But this is not heredity, even in the very loosest way in which the word is used by medical men."

Hospital Sunday Collection.—The total amount obtained this year by the Hospital Saturday and Sunday collection was $50,408.10. Deducting expenses, the net amount is $43,500 left for distribution, which is $6,500 more than was obtained last year.

The Crown Prince.—Sir Morell Mackenzie reports formally, under date of February 12th, his opinion on the condition of the Crown Prince. He summarizes his views as follows: "In my opinion, the clinical symptoms have always been entirely compatible with non-malignant disease, and the microscopical signs have been in harmony with this view. I need only add that, although in nearly every case of laryngeal disease it is possible at the first inspection to form an accurate opinion as to the nature of the disease presenting itself, yet in a few rare instances the progress of the complaint alone permits its character to be determined. Unfortunately, the case of His Imperial Highness is among the latter number, and at this moment medical science does not permit me to affirm that any other disease is present than chronic interstitial inflammation of the larynx combined with perichondritis." In his report on the examination of the slough which came from the larynx, Professor Virchow says: "I could not determine what kind of morbid process had caused the gangrene, nor what kind of process had produced the demarcation and exfoliation of the substance. Neither pus-corpuscles nor granulation-cells could be distinguished, and, in fact, in most places there was nothing of a heterogeneous nature to be discovered. Only in the larger of the two smaller pieces, which had been cut off the main mass by Dr. Krause from a somewhat hard spot, and which had the form of a flat wart on section, with the naked eye a central whiter and an external and opaque, rather thick covering could be distinguished. In every microscopic section so-called nests (*Zwiebeln*) of epidermoidal cells, for the most part of a homogeneous character, were seen. As a rule, these nest-cells were in the most external layer or in that lying immediately beneath it. The external layer had also most likely consisted of an epidermoidal formation, though these cells could only be here and there partially distinguished. I could not find epidermoidal cells in the deep parts, and distinctly isolated alveoli were nowhere to be discovered, in spite of assiduous researches."

A Book-agent with the Small-pox.—Dr. Porter sends the following item to the *Journal of the American Medical Association:* A case just brought to light illustrates in a striking manner the way in which people in a large city may be exposed to the danger of contagious diseases without any suspicion on their part or of those liable to communicate the infection. A book-agent applied at the dispensary of the New York Polyclinic for treatment for what he supposed was some ordinary form of skin disease, but which was found on examination to be small-pox. After being removed to the Reception Hospital the man stated that he had been sick ten days, and that during the whole of that time he had been canvassing for subscriptions to a book; visiting mainly banks, insurance companies, and other business offices in the lower part of the city.

The Opening of the Loomis Laboratory.—The Medical Department of the University of the City of New York is to be congratulated upon the completion of the Loomis Laboratory. The new structure, adjoining the other buildings of the medical department to the east and communicating with them, has been erected at a cost of over one hundred thousand dollars, and is the gift of a friend of the University, whose modesty equals, if it does not exceed his generosity. It is constructed according to the most approved methods, has an air of solidity, and is admirably adapted to the uses for which it is intended. The floors throughout are water-proof, the wood-work of cherry in natural finish, and the walls finished in soapstone, of a tint most pleasing to the eye. The building is 35 feet by 90, and five floors in height. The first floor is devoted to the laboratories of materia medica and of physics. The physical laboratory communicates with the lower lecture-room of the main college-building, and affords exceptional facilities for the illustration of the lectures in physics and chemistry. The physical cabinet is well supplied with apparatus. The second floor is devoted to the chemical and toxicological laboratories, divided into a large general laboratory, with desks fitted with gas, water, and ventilating outlets, capable of accommodating sixty students, a balance-room for weighing, a laboratory for the investigation of cases of poisoning, and a laboratory of research, fitted with modern chemical apparatus. The third floor is divided into a large physiological laboratory in the front, which communicates with the amphitheatre of the main college building, for convenience of illustration of the lectures on physiology. This laboratory is well arranged for original investigations, although we failed to find in it the modern apparatus without which physiological investigation is difficult. We trust that the loss of the complete outfit in this department, formerly possessed by the college, will soon be repaired. The laboratory of histology occupies the south half of the third floor, and is furnished for the commodious accommodation of thirty students, each of whom is supplied with a microscope and all other requisite apparatus, and is abundantly supplied with well-selected histological material. The fourth floor is devoted to pathology, the south half being arranged for undergraduate teaching, and the north half fitted with all requisite apparatus and fittings for advanced work and original investigation. The fifth floor is subdivided into a laboratory of bacteriology, a pathological museum, and rooms for photo-micrography, and for such special investigations as may be found to require separate rooms. We understand that the donor purposes to complete his gift by endowing the laboratory with a sum sufficient to meet all running expenses. Not only is the University interested in this laboratory, but also the profession in general and the public at large, as it is the intent of the donor, in which he is seconded by those having the laboratory in charge, that facilities shall be here furnished for those desiring to engage in original investigations, and we trust in time to welcome the appearance of the results of such labors.

The People's Medical Service Society, of New York, has been incorporated by Munsell H. Peet, Louis E. Hilborn, Eva Walton, George W. Hopkins, and D. Edgar Anthony. The capital stock is $12,000. It proposes to furnish medical aid to laborers and people of moderate means. The institution is believed to have purely business objects.

Society Reports.

MEDICAL SOCIETY OF THE COUNTY OF NEW YORK.

Stated Meeting, February 27, 1888.

Laurence Johnson, M.D., President, in the Chair.

THE PAUPER INSANE.

Dr. Samuel Sexton explained the nature of a bill presented to the State Legislature by the State Charities Aid Association, providing for the care of the pauper insane in State institutions, and offered resolutions approving of the bill. The resolutions were adopted.

Dr. Charles W. Allen read a paper on

LEPROSY IN THE UNITED STATES, AND ITS RELATION TO THE STATE.

In replying to the question, Why should we stop to discuss a disease which appears of so little practical importance to us, the author reviewed the history of the disease in the United States, and considered whether the facts justified us in regarding it as a source of danger of national importance. The earliest cases of leprosy in this country appeared in Louisiana and South Carolina. Later it had appeared in the Northwest, where it was brought from Norway, and also in California and the West, being brought there by the Chinese. It has also occurred among natives who have visited foreign lands where the disease is prevalent, and a few sporadic cases have appeared among our own people without known origin. At least five sporadic cases, occurring in the United States, were on record. Dr. Allen thought it was not an overestimate to say that there are in this country to-day at least one hundred and fifty cases.

He regarded this as one of the most favorable countries in which to study leprosy. In addition to the review of cases already reported, the histories of two unrecorded cases were given, and one of the patients presented. The other patient had come under the care of Dr. Wiener, but was then in Paris. The further histories of some cases reported by Dr. H. G. Piffard in 1883 were also given. The patient presented had certain disfigurements of the face, especially over the eyes, due to the progress of the disease, which had led Dr. Allen to institute surgical interference for cosmetic effect. The improvement in looks had been considerable. He did not believe the progress of the disease would be any more rapid on account of such surgical interference. The results of treatment in a number of cases reported in this country had been markedly beneficial, especially that from chaulmugra oil, and led to the belief that these cases are less hopeless than they have hitherto been regarded.

The author then took up the subject of the contagious and hereditary character of the disease. While the majority of physicians, especially those residing in leprous countries, disbelieved in the contagious character of the affection. most of them did believe it to be hereditary. But Dr. Allen cited well-authenticated instances in which the children of an affected parent, continuing to reside with their parents, contracted the disease, while those of the same family who were taken from their parents while yet young remained well. This went to show that in some instances, at least, the cases supposed to be of hereditary origin were in reality of infectious origin, the infection taking place in the intimacy of family life. Similar clinical evidence of the infectious nature of the disease was given.

The proof of infection by experiments had not been satisfactory. The author thought there was pretty positive evidence to show that leprosy had been spread, in a few instances, by careless vaccination against small-pox, the vaccine virus having been taken from those affected with leprosy. The mistake had often been made of looking for the evidence of the contagious nature of the disease too early.

Believing, as Dr. Allen did, in the infectious nature of leprosy, the question arose as to the advisability of segregation of the lepers in the United States. The right of the individual to personal liberty is one most zealously guarded in this country, and should not be taken away without good cause.

If it is right to segregate lepers because leprosy is an infectious disease, why is it not also right to segregate those who have syphilis and tuberculosis, which diseases are likewise infectious? The author replied to this question by saying that, if it were possible to eradicate syphilis and tuberculosis from our country by segregating those affected with these diseases, he would approve of its being done. But this might be impossible of these two diseases, which have so strong a hold on our population, while it would be quite possible regarding leprosy, of which there are but few cases yet in this country. It was just to sacrifice the interests of the individual when the good of the whole people demanded it.

Dr. George H. Fox had seen a number of lepers in this country, and many more in leprous communities or hospitals in Norway and other countries, yet he was unable to speak positively of the hereditary, contagious, climatic, or hygienic nature of the disease. The majority of physicians were opposed to the view that it is contagious; individually, he was of the impression that leprosy is both congious and hereditary; but it is only very mildly contagious, and for that reason he did not think we were justified in this country in depriving the leper of his liberty and association with other people. There was no occasion, he thought, for fearing a spread of leprosy throughout this country. Dr. Fox did not believe that leprosy is incurable. The benefits of chaulmugra oil in his hands had been marked. He cited one case in which it had resulted in cure. But if the patients were imprisoned with those suffering like themselves, deprived of all hope in this life, neither chaulmugra oil nor any other measure would be likely to prove of any benefit.

Dr. P. A. Morrow said his own impression was that leprosy is contagious, and is also transmissible by inheritance. Yet we know very little about how the germs conveying the disease gain access to the system; whether they come from direct contact with the abraded surface of the diseased, through the air, water, or contaminated articles. There had not been a single case in which the disease had been acquired among the patients of Charity Hospital who had associated with the lepers in that institution. In 1867 the opinion was formulated by the Royal College of Physicians, in England, that leprosy is non-contagious. The majority of physicians who have seen most of leprosy believe it to be non-contagious. While these facts did not prove to Dr. Morrow that leprosy is non-contagious, they did prove that it must be only mildly so, and he thought we might eliminate it as a possible cause of spread of the disease; and he did not think the State was justified in this country in segregating these patients. We should not take leprosy as it exists in the Sandwich Islands as a basis of comparison with the probable course of the disease in this country. The surroundings and the manner of living are entirely different. Leprosy in Norway is dying out, yet the patients there are not strictly segregated; even after their admission to an institution they are still at liberty to go out and associate among their friends.

Dr. D. B. Delavan thought the question should be studied from three different stand-points: First, is leprosy contagious or communicable. Second, is it communicable at all times in equal degree. Third, what has been the result of segregation?

While the disease may not have been shown to be very contagious, yet its history in Europe during the middle ages formed a most instructive chapter. Its ravages then were most terrific, and extended to all parts of Europe. Have we proof that a similar epidemic may not some time develop in this country? History went to show that wherever the disease has prevailed, segregation has been found desirable. Dr. Delavan expressed faith in treatment, especially by chaulmugra oil.

Dr. Henry Koplik had seen only a few cases of leprosy, but he questioned whether surgical interference, as practised in Dr. Allen's case, might not hasten the progress of the disease, as it was believed to do by some in the case of tuberculosis, which he regarded as an allied affection.

The author closed the discussion, after which the Secretary presented a communication from the Georgia Medical Society, together with the following resolutions, which, on motion, were adopted:

Whereas, The feeling of humanity suggests that all medical and surgical supplies, instruments, and appliances, including those used in diagnosis as well as in the treatment of disease, should be furnished to those needing them at the lowest possible price;

Resolved, That the Medical Society of the County of New York would urge upon Congress that, in the cause of humanity, the import duty should be removed from all medicines, medical and surgical appliances, and from everything used in the treatment and diagnosis of disease.

Adjourned.

The Pneumatic Cabinet *vs.* the Gasometer.—Dr. S. Solis-Cohen, writing in the *Journal of the American Medical Association*, states that the objects accomplished by the pneumatic cabinet may be accomplished also by other means, such as the Waldenburg apparatus, the gasometer apparatus, etc. He adds that: "In view of the recorded history of pneumatic treatment, and of the facts that the pneumatic cabinet is a 'patented remedy;' that it has no advantages, physically or clinically, over other apparatus; that it offers less mechanical facilities for variations of method; that the patient is shut away from examination and control during treatment or from prompt assistance in case of accident; that the cost of the cabinet is out of all proportion to the cost of other instruments, thus tending to prevent rather than promote the extension to all needing it of the benefits of this plan of treatment, we respectfully submit that, while those who prefer the cabinet upon commercial, æsthetic, or mechanical grounds are entitled to use and express that preference, they are not justified, either by recorded facts or physical principles, in claiming novelty or superiority for the instrument, its therapeutic methods, or its clinical results; or in representing as the beginning and the end of the science of pneumo-therapy an instrument which is simply a comparatively unimportant incident in its development."

The Indiana Medical Journal tells of an American in Paris who was about to die. He ordered the following despatch sent by cable as soon as the last breath left his body: "Am dead. Corpse will follow by next steamer."

NEW YORK PATHOLOGICAL SOCIETY.

Stated Meeting, February 8, 1888.

W. P. Northrup, M.D., President, in the Chair.

The President presented, on behalf of a candidate, specimens removed from the body of a child that had died of *tubercular meningitis with general tuberculosis.*

Dr. G. R. Lockwood presented, on behalf of a candidate, a specimen of *hour-glass uterus.*

Dr. F. S. Sellew presented the history of a case of

CHRONIC BRIGHT'S DISEASE WITHOUT ALBUMINURIA.

The patient was a woman, aged sixty-two, unmarried, temperate; had been failing in health for five or six years, "but no doctor was able to tell her what was the matter." Two years ago she came under observation. At this time she was in fair flesh, very anæmic. No stomach symptoms, no headache. She complained of nothing except weakness in the knees. She could not walk as far as formerly, and yet went about out of doors. She said that her urine had been examined by six doctors, and that no one had found anything wrong with it. Repeated examinations made by Dr. Sellew gave the following results: Amount passed in the twenty-four hours, twenty-four ounces; specific gravity, 1.015, acid, pale, or amber-colored; no albumin, no sediment; no casts were ever found. During the last week of life a trace of albumin appeared.

There were no symptoms up to within three weeks prior to her death, save a gradually increasing feeling of weariness and exhaustion, together with increasing pallor. The pulse was regular and of normal tension until the last three weeks of her life, when there were occasional attacks of palpitation.

At this time there was diarrhœa, which alternated with œdema of the feet and ankles, but there was no ascites. There was occasional vomiting and moderate headache, but the principal symptoms of which the patient complained were excessive weakness and weariness. The pallor gradually increased and became waxy in nature.

The diagnosis of chronic Bright's disease was made at the outset, on the characteristic waxy pallor and the low specific gravity of the urine, and was later confirmed by the occurrence of vomiting and the œdema of feet and ankles, alternating with diarrhœa.

The autopsy, made twelve hours after death, by Dr. W. P. Northrup, showed the following: The heart was pale and flabby, and contained decolorized clots; the muscle substance was so softened that the finger with moderate pressure could be easily thrust through both walls of the cavities together. The liver was slightly diminished in size, the surface of a chocolate color, finely nodulated and firm. The kidneys were small, the surfaces lobulated and finely granular, the capsules bringing away bits of tissue when stripped off; the cortex was of normal thickness, pale and firm.

The microscopical examination showed the heart muscle to be the seat of advanced fatty degeneration.

In the kidneys there was diffuse interstitial thickening with atrophy of the tufts, contraction of some of the tubules, and dilatation of others.

The epithelium was broken down and had disappeared in some of the tubules, and there were hyaline casts in many. These might have appeared in the urine from time to time, and easily have escaped discovery.

The anatomical diagnosis was made of: 1, Chronic diffuse nephritis; 2, advanced fatty degeneration of the heart; 3, cirrhosis of liver.

The points of special interest in the case were thought to reside in: 1, The absence of anything abnormal in the urine upon repeated examination of several doctors; 2, the characteristic waxy pallor, and, 3, the well-marked lesions shown by the autopsy.

Dr. Sellew also presented specimens, removed from the body of a child who had died from

PLEURO-PNEUMONIA, COMPLICATED WITH PLEURISY WITH EFFUSION OF THE OPPOSITE SIDE.

Fidelis M——, aged nine months, was brought to the out-door department of the New York Foundling Asylum on January 30, 1888, suffering from diarrhœa and vomiting, and with inflammation of both tonsils.

The child was wet-nursed and was fairly well nourished. On February 1st, the diarrhœa and vomiting were relieved, but the tonsils were still greatly swollen, though there was no membrane. On February 3d the tonsillitis had begun to subside, but there was a short cough, with labored respiration, and on the right side dulness and bronchial breathing were present. The dulness was not marked, nor did it extend over a large area of lung. On the left side there were a few coarse mucous râles.

On February 8th the child was returned to the Asylum in collapse, and died soon after.

At the autopsy it was found that the left lung was compressed by pleuritic effusion, there being three ounces of turbid serum in the pleural cavity. Upon the surface of the compressed portion of the lung there was a thick exudate of pus and fibrin. The only aërated portion of the lung was the anterior half. The right lung was the seat of an extensive and severe pleuro-pneumonia, the entire lung being in a condition of red hepatization, without any aërated portions. The other organs, even the heart, were normal.

The interesting features of the case were the two associated conditions found in the two lungs. In one there was pleurisy, with effusion of serum and fibrin, with compression of the lung, but no pneumonia. In the other side was an extensive pleuro-pneumonia, the only aërated portion of the lungs being the anterior half of the left or compressed lung. It was thought that the disease commenced on the right side, and was complicated later on by the pleurisy with effusion.

It was also interesting to note the absence of pericarditis. It is very common in autopsies at the New York Foundling Asylum, in extensive inflammation of both lungs or in extensive pleural fibrinous exudates, to find associated pericarditis with excess of fibrin.

The President remarked upon the two especially interesting points in connection with this case. The first was the extremely severe nature of the lesions. The pleurisy with effusion compressing the lung on the left side, and the pneumonia with pleurisy on the right side, rendered both lungs almost useless, and for the last few days of life the breathing space was limited to a small portion of the right lung. The second point of interest was that the pericardium was entirely free from disease, although the pleural surfaces on either side of it were inflamed.

Dr. J. Lewis Smith said that it was not uncommon to find the pericardium involved under these circumstances, yet such was not the invariable rule. He thought it would have been interesting to study the physical signs present in this case. He also inquired whether there were any tubercles present.

The President said that unfortunately there was no clinical history of the case. He did not know which side was first affected, but for the few days immediately preceding death there would probably have been little in the way of physical signs except dulness on both sides. No evidences of tuberculosis had been found at the autopsy.

Dr. Mary A. Dixon Jones presented the

TUBES AND OVARIES

removed by operation from a woman, twenty years of age, married three years, no children. She suffered not only at the menstrual period, but in the intervals as well, with distress and pain in the pelvis. Laparotomy was performed, and the tubes and ovaries were found bound down by adhesions. The tubes were enlarged, closed at each end, and apparently filled with pus.

Dr. Jones also presented another specimen, removed from a woman thirty-eight years of age, the mother of four children, the oldest ten, the youngest five years of age. The patient suffered much pain, and was not able to attend to her ordinary household duties. The cervix was found, on examination, to be deeply lacerated and widely gaping, as if the uterus were pulled in some unusual position. Apparently all around the cervix was a solid mass, having a radius of three and a half to four inches, and extending down on either side to the anal region, and upward as high as the top of the pubic bone. In some portions this tumor was so solid that it suggested a fibroid, but other portions were soft and even fluctuating.

THE UTERUS WAS PULLED OVER TO THE RIGHT,

and firmly fixed, seeming to be closely adherent to the mass about it. The sound could be passed up a distance of four inches.

When the abdominal cavity was opened the uterus was found fixed and deflected toward the right, the right appendages being below it and deeply embedded in adhesions. To the left of the uterus there was a solid mass occupying the whole left of the pelvis, and closely fixed and bound down by adhesions. That portion of the appendages originally anterior was turned over and adherent to the back of the pelvis, and was covered by the remains of strong and well-organized adhesions, which had to be separated with the greatest care on account of some being adherent to the rectum. The greatly enlarged tube, which occupied the lower part of the mass, after going a straight course of three inches, bent upon itself at a right angle and extended upward for another three inches, measuring altogether five and a half to six and a half inches in length. The lumen of the fimbriated extremity measured an inch and a half in diameter, being large enough for the entrance of the index-finger. By this turning over the posterior portion of the appendages had become the anterior, and, being closely united to the anterior wall of the pelvis, had thus formed a cavity, and it was here that the sense of fluctuation had been obtained. There were several other large cysts similarly formed by inflammatory adhesions. The whole of the mass was removed and the abdominal cavity was washed out, but the pedicle was so large and so fibrous that even after tying it still bled, so it was fixed in the abdominal wound by Koeberle's clamp.

The organs had not yet been examined microscopically, but the nature of the changes present might be inferred from those found in a case having similar general features upon which Dr. Jones had operated. The patient was twenty-one years of age, married, and had two children. She menstruated first at the age of eleven years, and then, and ever since, had had severe pain, showing that she had begun her menstrual life with diseased ovaries. Since the birth of her last child the menstrual pain had increased in severity. The cervix and perineum were both deeply lacerated, and on account of the youth of the patient it was determined to repair these structures first, in the hope that the condition of the woman might be thereby so far improved as to render her life endurable without taking from her the possibility of future child-bearing. The operation was, however, not successful in producing this result, so the removal of the ovaries was decided upon. The appendages, which were buried in the midst of adhesions and extensively diseased, were also removed. The tube was enormously enlarged, especially at the fimbriated extremity, and completely closed. There were extensive adhesions back of the tube, and between it and the ovary, and numerous cysts had been formed in this new inflammatory tissue. The ovaries were small and buried in adhesions. Microscopical examination showed degeneration of the ovary from chronic ovaritis, the entire structure being changed except a small portion at the periphery. The tube was diseased in all of its structures—mucosa, connective tissue, muscular tissue, and peritoneal investment.

In many places the perimysium was almost wholly destroyed, and the smooth muscle-fibres of the tubes were entirely disintegrated by the inflammatory exudate. In many places the leucocytes were so crowded together as to form true abscesses, no vestige of muscular tissue being left. In other places, under the microscope, the muscle fibres presented the appearance of a few broken fragments floating in a sea of inflammation corpuscles.

Dr. Jones objected to the term

INTERSTITIAL SALPINGITIS,

usually applied to this condition, as it was not the interstitial connective tissue that was affected, but the muscle itself. She thought the term "corporal salpingitis" would be more appropriate.

Salpingitis usually begins in the mucous lining of the tube and travels outward, but in this case the periphery was most affected, evidently by continuity from the peritoneal inflammation, while the mucosa was least involved.

It was perhaps of interest to add that the patient had at times suffered from great mental depression, and had often threatened self-destruction, but since the operation these symptoms had disappeared, and she had gained steadily in health and strength. Dr. Jones believed that in very many cases similar to this, of supposed uterine disease, the most serious trouble was really with the ovaries or tubes.

Dr. J. Lewis Smith presented a specimen of

UMBILICAL PHLEGMON,

removed from a child who had died in the New York Infant Asylum. Diphtheria had appeared in this institution in August last, since which time there had been in the neighborhood of thirty cases of the disease, and among them were four in the new-born. During the same period there had been six cases of umbilical phlegmon, a most unusual number for that institution.

The patient, Violet M——, was born on January 5th. There was nothing unusual about the labor, and the mother has done well—indeed in all these cases of umbilical phlegmon the mothers had done well. The navel was dressed with borated cotton, according to the routine habit in the Asylum. On January 11th the baby was noticed to have a slight discharge from the umbilicus. Its temperature at this time was 100°. The following day there was some redness immediately about the umbilicus, and this extended gradually until, on the day succeeding, it covered an area with a radius of an inch and a half around the navel. On January 14th examination of the fauces revealed the presence of

DIPHTHERIA.

The temperature ranged from 98.3° to 101.2°, the pulse was weak and varied between 120 and 146. The throat was sprayed with a mixture of sodium benzoate and sodium bicarbonate, of each ʒ ij.; Listerine, ℥ j.; glycerine, ℥ ij.; and lime-water, ℥ viij. The exudate did not disappear under this treatment, however, and on the following day—when the patient died—it had extended to the nostrils.

Post-mortem examination.—The diphtheritic exudate was found covering the epiglottis, especially its under surface, and extending into the larynx down to a point just below the vocal cords. The lungs were mottled with hemorrhagic points. The umbilicus had been sent to Dr. Prudden for examination.

Dr. Smith regarded the occurrence of such an unusual number of cases of umbilical phlegmon during the local epidemic of diphtheria as a point of considerable interest, and he thought it would be of great value to determine whether there were any causal relation between the two.

As a matter of prophylactic interest, he said, it was worthy of mention that there had been no more cases of diphtheria since use had been made of turpentine steam in the institution. A mixture was prepared of oil of eucalyptus ʒ ij. to iv.; turpentine, ℥ viij.; and water, Oij. This was kept in a constant state of ebullition night and day. If this were done everywhere he believed that there would be no danger of the physician carrying away the infection in his clothes.

Dr. Prudden reported as follows upon the specimen: A section through the abdominal wall parallel with the abdominal vein showed that the interstices of the abdominal parietes about the vein were densely infiltrated with serum, fibrin, and pus, and that a small red clot was firmly lodged in the outermost portion of the vein.

SECTIONS STAINED FOR BACTERIA

showed large collections of micrococci at one side of the clot in the vein, with a necrosis of the inner layers of the vein near the bacteria.

Furthermore, the exudation mass in the tissues outside of the vein, particularly along the adventitia, was intermingled with large numbers of micrococci, either scattered singly or lying in clusters or in larger and shorter chains.

Cultures made from the clot and from the exudation showed that two species of micrococci were present, which were readily identified as the *streptococcus pyogenes* and the *staphylococcus pyogenes aureus*.

As to the relationship between these bacteria and the diphtheritic process which developed later in the throat, Dr. Prudden could only say that, as we do not yet know what bacteria cause diphtheria, a definite opinion must be held in abeyance.

Dr. J. S. Thacher presented a specimen of

LARGE TUBERCULAR MASSES IN THE PERITONEAL CAVITY,

which had been sent to him by Dr. Montague L. Boyd, of Savannah, Ga., with the following history:

The patient was a negro girl, five years of age. The mother stated that the child had complained of pain in the abdomen two years ago, and that she had noticed a lump there which was tender on pressure. The case had been under observation for six months. The abdomen had been very much enlarged, the rest of the body being extremely emaciated. The bowels were regular, and the appetite fair. The temperature was almost constantly elevated, ranging from 101° to 103°. There was no œdema of the face or limbs, and no cough at any time. The abdomen became more and more enlarged, while the rest of the body gradually wasted away, the strength failed by degrees, and the child died without any other symptoms.

Dr. Boyd's diagnosis of the case was sarcoma, while other physicians who had seen the child suggested malarial enlargement of the spleen and ovarian tumor.

The autopsy was made under adverse circumstances, and only the abdomen was opened. The peritoneal cavity contained about two gallons of a thin milky fluid. The tumor, with intestines, stomach, and spleen, was removed. The tumor was seen, on inspection, to be composed of a number of rounded nodules, some fused together and some separate from the rest. The tumor measured about $5 \times 3\frac{1}{2} \times 3$ inches, the largest distinct mass being about $4 \times 2\frac{1}{2} \times 2$ inches, and the others of all sizes less than this. They lay behind the peritoneum, in the mesentery, and in the omentum, and gave the impression of being enlarged lymphatic glands. On section they were found to be of a firm, cheesy consistence, and of a pale yellow color.

Under the microscope they were seen to be made up, for the most part, of a structureless granular mass, but at the circumference of inflamed connective tissue, having the features of tubercular inflammation fairly well marked. A very few tubercle bacilli were also found in the sections.

The Society then went into executive session.

Metrorrhagia following a Dose of Quinine.—Dr. A. C. Follett, of Huron, Dak., reports that one of his patients took, upon her own prescription, ten grains of quinine to cut short a commencing cold. In about half an hour she began to suffer from nausea, vomited freely, and was soon greatly prostrated. About an hour later a profuse metrorrhagia set in, and continued for three or four hours.

Correspondence.

OUR LONDON LETTER.

(From our Special Correspondent.)

A MEDICAL SPORTSMAN—DISPUTES ABOUT POST-MORTEMS—INTESTINAL SURGERY—THE DIAGNOSIS AND TREATMENT OF RUPTURED INTESTINE WITHOUT EXTERNAL WOUND—RUPTURE OF COLON OUTSIDE PERITONEUM—NÉLATON'S OPERATION FOR INTESTINAL OBSTRUCTION—RELAPSING TYPHLITIS AND ITS TREATMENT—THE BRITISH NURSES' ASSOCIATION.

London, February 18, 1888.

A year or two ago an article appeared in one of the magazines with the title "Doctors out of Practice." More medicos are out of practice—*i.e.*, either retired or engaged in other avocations—than would be credited. There is, in fact, scarcely any calling in which medical men have not engaged. Among other pursuits sport has drawn no inconsiderable contingent from our profession, including at least one doctor who devoted himself to it so exclusively as to make it his real profession. I refer to Mr. Walsh, the well-known editor of *The Field*, who died recently. Born in 1810, he studied at Guy's, and became first a Member, subsequently a Fellow, of the College of Surgeons of England. After nearly twenty years of country practice, he spent some time in travel, and finally settled down in London. He became connected with the sporting journal *Bell's Life*, and afterward became editor of *The Field*, a post which he held for thirty years. Besides his editorial work he found time to pen several treatises on sport, writing under the pseudonym of "Stonehenge"—a name recognized as an authority on all matters pertaining to sport by sporting men far and wide.

The performance of a post-mortem examination in a private house is not, at the best of times, a very pleasant process. It is often far from easy to gain the consent of relatives to such a procedure, and even when their compliance has been obtained it is no easy task to make a complete autopsy without leaving unpleasant traces of what has been done. It is very regrettable where the interests of science have induced a medical man to make such an examination without the consent of, or sometimes in defiance of, the relatives or friends. Such incidents are happily of infrequent occurrence. One such has, however, recently occurred at the West End of London. The medical man in attendance did not himself make an autopsy, but sent another doctor to do it. The latter made the examination, and took away with him some of the organs. He left behind him, however, his post-mortem case, which the enraged relatives took possession of, and refused to deliver up. The owner applied to the police-court of the district. The magistrate advised the surrender of the case, which was accordingly returned to its owner. It transpired that the medical man in attendance had been appointed one of the executors by the deceased, and the magistrate remarked that one executor had as much authority over the body as another. Further light was thrown on the matter subsequently by a letter from a son-in-law of the deceased which appeared in *The Times*. In this it was stated that the medical man who ordered the post-mortem examination was, it was true, an executor, but that he could not have been aware of this fact at the date of the autopsy; that the doctor who made the examination gained access to the body by a pretext, and that he left the house with an untruth upon his lips, viz., that he had not done anything to the body.

Intestinal surgery occupied the attention of the members of the Clinical Society at their last meeting. Mr. Mayo Robson read a paper on the diagnosis and treatment of ruptured intestine, in cases where there was no external wound. He described six cases, and observed that in some the symptoms were so distinct as to be almost pathognomonic. The combination of symptoms to be most relied on were shock closely following upon an accident, abdominal pain, moderately quick and soft pulse, vomiting of contents of stomach followed by bilious vomiting, anxious countenance, and diminished or *absent* liver dulness. No reliance could be placed on expectant treatment, and Mr. Robson remarked that the only hope of success lay in early operation. He had himself adopted the rule that where there was a reasonable belief that the intestine was wounded, a small median incision should be made. If there were any rupture of the bowel, flatus, or serum tinged with blood or fæces, would escape through the small peritoneal opening, which could then be enlarged if necessary. If, on the other hand, no such escape took place and the peritoneum proved to be healthy, the small wound could be closed and no harm would have been done.

Mr. Golding Bird remarked on the diagnostic value of radiating pain as insisted on by Mr. Poland. He thought that in such cases the liquid and solid food given to the patient should be of the smallest possible quantity. Much liquid might result from the melting of ice sucked by the patient, and he had known the peritoneum to contain much blood-stained ice-water. Mr. Bryant spoke of the value of treating as serious all cases of abdominal injury. Sir William MacCormac thought the dictum right, "when in doubt, operate." Mr. Bennett thought a week not too long to watch cases of suspected rupture, and related the case of a boy aged fifteen, who was struck in the loin by a cricket-ball, and had no symptom except slight tenderness there. He was kept in bed for a week on spare diet. He then seemed well and was allowed to get up. Faintness came on soon and he died. The necropsy showed that the duodenum had been torn across, but the tear had not implicated the peritoneum till the fatal issue. Mr. Bennett narrated a case of intestinal obstruction in which the colon gave way outside the peritoneum. An operation was performed to relieve the extreme distention, but fatal collapse ensued. Mr. Walsham then read a case of intestinal obstruction treated by Nélaton's operation.

Intestinal surgery also occupied the attention of the Medical and Chirurgical Society at its last meeting, the subject under discussion being relapsing typhlitis and its operative treatment. A paper by Mr. Treves was read, in which the opinion was expressed that relapsing typhlitis was due, in most cases, to some appendicular trouble, and that it might therefore be relieved by operation during the period of quiescence following an attack. A case thus successfully dealt with was narrated. Mr. Holmes mentioned a case in which he had operated. Mr. Howard Marsh thought it a valuable suggestion that a number of affections in this region having various names were due to the state of the appendix. Mr. Walsham said he had been for some time coming to the conclusion at which Mr. Treves had arrived. Mr. Hulke referred to a valuable paper by Dr. Sands, of New York, in which prompt and early interference was advised in cases diagnosed as disease of the vermiform appendix. Dr. Douglas Powell observed that typhlitis and perityphlitis were as distinct as pneumonia and pleurisy. Dr. Dickinson thought that perityphlitis was due chiefly to diseases of the appendix.

A numerously attended and influential meeting in support of the recently formed British Nurses' Association was held a few days since. Mr. Savory, F.R.S., President of the Royal College of Surgeons, occupied the chair. He said it would be the object of the association to obtain a charter. By legal registration it would guarantee the efficiency of nurses; by deliberation and discussion it would advance the great work of women; by the judicious distribution of distinctions, it would bring to the front those worthy of such a position; and it would provide for its own members in old age and sickness.

INSUFFICIENCIES OF THE OCULAR MUSCLES.

To the Editor of The Medical Record.

Sir: In examination of the conditions of the ocular muscles in some thousands of cases I have found that one in which there exists insufficiency of the interni "of more than 18°" associated with manifest insufficiency of the superior rectus from 5° to 7°, is presumably one of strabismus. We know that von Graafe operated on the superior rectus, "in the interest of binocular vision," as he doubtless did in the case reported by Dr. Derby in your last issue.

In regard to the assertion that relief to non-strabismic insufficiencies of the superior or inferior rectus "has been the common property of all competent ophthalmic surgeons for at least twenty years," it is sufficient to say that operative measures of this character, which are the "common property" of a considerable number of competent persons, are liable to find their way into the literature of the subject to which they are naturally related in considerably less than twenty years; and there is little occasion to prove the title to such common property by a search after what a recent writer, referring to these conditions, characterizes as "unpublished exploits."

Ordinarily it is a very difficult matter to prove a negative. In respect to the claim of Dr. Derby that such operative measures have been the "common property of all competent ophthalmic surgeons for at least twenty years," it would be quite easy to show that the statement is incorrect.

George T. Stevens.

33 West Thirty-third Street.

THE RESULTS OF JURY TRIALS IN LUNACY IN THE STATE OF COLORADO.

To the Editor of The Medical Record.

Sir: In your editorial of January 21st, you make use of the following language, when speaking of a proposed law to have jury trials in all cases of insanity before commitment: "Such a process would be clumsy, expensive, and dangerous, and is quite uncalled for." That is *ex-cathedra*, sure enough. In Colorado we have just such a law, and we do not have the scandals that you have in New York State about sane persons being confined as insane.

Here the medical man goes before a jury and gives his testimony in the presence of the person. A guardian *ad litem* is appointed, the person supposed to be insane is allowed to ask questions, and they often do so, and if insane usually give themselves away.

The jury weighs the testimony, and a verdict is rendered; the physician goes home without fear of a coming prosecution, the patient goes away far more quietly than when spirited away by a secret star-chamber proceeding, even though ever so justly conducted. But few patients are so insane as to not know when they have had a fair trial, in which relatives and meddlers have not had it all their own way. Hence they acquiesce in the results, though often denying the correctness of the trial.

Now, as to the "clumsiness" of such a proceeding, it is quite expeditious, occupying but a few hours, and nine out of ten patients accept service, thereby waiving the legal ten days' delay if service is denied. As to expense, when the parties are unable the county pays all expense, which in this State of excessive court fees averages fifty dollars.

The workings of this law have thus far protected the rights of both patient and community. I have resided here for the past sixteen years and never heard of any ill-workings of this law; and what is better, never been sued or known of any other practitioner being sued by a patient or a friend. The jury trial protects the physician, and when the patient recovers there is no ill-will toward the doctor. I have never known any injury being done to the patient or his mental condition by a public trial;

but few attend such trials, and the patient is not unduly excited, at least not any more than his real interests justify.

In conclusion I ask, In these days of two-term medical students being turned loose upon an unsuspecting community, would you, Mr. Editor, be willing to have the average medical man examine you as to sanity and have the power to consign you to an asylum?

Where the vicious "insanity-certificate" method originated they have a much stricter examination, as well as method of education, before they give their medical men such dangerous power. When we stop trying to regulate medical practice, and seriously regulate some of our so-called medical colleges, it will be time enough to give our physicians the dangerous power your New York State laws give them. Until then the jury trial, in insanity cases, of Colorado is the best, that is, if we judge by its results.
CHARLES AMBROOK, M.D.

BOULDER, COL.

WINTER ITCH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: In your editorial of January 14th mention is made of winter itch. Perhaps my personal experience with that agreeable companion may be of interest.

During the winter of 1879–80 my horse slipped his halter and took French leave. After a hard run of half a mile the animal was caught. As I stepped into the cutter the horse became frightened and attempted to run away. I was perspiring very freely, the day was bitter cold, and the horse requiring all my attention, I could not properly wrap myself in the robes. Thus I travelled for about half an hour, facing a piercing northwest wind, and alighted from the sleigh thoroughly chilled.

No inconvenience was experienced for a day or two, after which those portions of the limbs which were most exposed commenced to itch. Soon the pruritus located itself permanently in the extensors of the thighs. No inconvenience was experienced during the day, but at night—especially after standing near a glowing coal stove—saints deliver us! there are no words in written language that would describe the pruritus.

Each winter, after severe exposure, the itch has returned and continued until spring. The skin is perfectly healthy; no lesion whatever is visible. My health is perfect, and has been all the time. Treatment has had no effect. The greatest relief has been obtained from wearing very heavy flannel underclothing. That is all I have tried for the past few winters, being fully resigned to fate, resolved to scratch it out.
⁂

FRANKLINVILLE, N. Y., January 21, 1888.

SOME EXPERIENCES WITH WINTER ITCH.

TO THE EDITOR OF THE MEDICAL RECORD.

SIR: *A propos* of an article in THE MEDICAL RECORD, January 14, 1888, on "Epidemic Winter Itch," I will state that within the past five years in this city I have seen as high as forty or fifty cases of Winter Itch. Over in Illinois they call it "Missouri Mange," and in Missouri it has been christened "Illinois Mange." It seems to be an eczema, followed with intense itching after retiring and getting warm in bed, and often begins before retiring when the patient becomes warm from any cause. I have found it to be mostly confined to the extensor muscles of the thighs and forearms, frequently covering the abdomen and around the scrotum, sometimes the back. I have never seen it on the face, feet, or hands. It usually selects those surfaces covered by the clothing.

I believe it is contagious, from the fact that I have known a whole family to be affected by it, or one person sleeping with another to impart it to his bed-fellow. In some cases I have seen it assume the pustular form on the forearms and wrists, and I believe it is transmitted from different parts of the body by inoculation with the finger-nails.

The etiology of the disease I am unable to account for, but I believe it comes largely from the want of baths, cleanliness, etc. I have pursued a course in the treatment that has proved *universally* successful. I prescribe as a local application (and always precede it with a warm scrub bath) chrysophanic acid ʒ iss. to the ounce of vaseline, this to be well chafed in at bedtime, wearing a suit of underwear that the stain will not affect. This is to be put on for three nights in succession, then take a good warm sponge-bath. In a few days the skin will peel off and the parts or surface will become quite tender, but that disappears in a few days. In the meantime I order ten drops of Donovan's solution three times a day. Within ten or fourteen days the most inveterate case will yield. After one week, if not cured, repeat the same procedure. I am safe in asserting that any one following this course will be relieved. There is no necessity of dieting or restricting patient in any way.
J. W. FOSTER, M.D.

KANSAS CITY, MO., January 16, 1888.

Medical Items.

CONTAGIOUS DISEASES—WEEKLY STATEMENT.—Report of cases and deaths from contagious diseases reported to the Sanitary Bureau, Health Department, for the week ending February 25, 1888:

	Cases.	Deaths.
Typhus fever	0	0
Typhoid fever	9	4
Scarlet fever	156	19
Cerebro-spinal meningitis	5	3
Measles	57	3
Diphtheria	98	38
Small-pox	3	1
Yellow fever	0	0
Cholera	0	0

COCAINE IN REMOVING A SCALP TUMOR.—Dr. B. Bowman, of Chambersburg, Pa., writes: "Some time ago, having occasion to remove an encysted scalp tumor where the usual anæsthetics were contraindicated, I injected along the line of incision, just under the skin, every three-fourths of an inch, about twelve drops of a ten per cent. solution of cocaine muriate. After waiting fifteen minutes, I found that making the incision, which was two and one-half inches long, removing the tumor, and putting in the stitches were entirely painless. It was situated on the left frontal eminence."

THE MEDICAL LANGUAGE OF MEXICO.—A writer in *La Emulacion*, a journal published in Guadalupe, Mexico, protests against the numerous barbarisms current in the writings and lectures of medical teachers in that country. Most of the ungrammatical expressions are, he says, Gallicisms, and he attributes them to the fact that the greater number of text-books in use there are written in the French language. In this country the tendency is rather to the adoption of Germanicisms.

LAICIZATION OF THE HOSPITALS IN PARIS.—The work of expelling the Sisters from the hospitals in Paris goes steadily on, despite the protests of the physicians and surgeons attached to the various institutions, who are naturally more concerned to have good nurses in care of the sick under their charge than are the politicians. The latest hospital to suffer in this way is the Charité. In the meanwhile the Prefect of the Rhone has awarded to Sister Chaumard, the Directress of the Maternity Hospital of Lyons, the honor of Officer of the Academy, on account of her unremitting labors, following the initiative of the physicians, in establishing a system of antiseptic midwifery in that institution.

TREATMENT OF CILIARY BLEPHARITIS.—Dr. W. Roeder observes that obstruction of the nasal duct and blennorrhœa of the lachrymal sac, as well as conjunctival inflammation, may occasion disease of the roots of the cilia, for the pus-cells combine with the stagnant tears and form an emulsion which easily overcomes the resistance of the fat of the sebaceous follicles and penetrates into the hair-follicles. The cilia then swell, and the inner hair-sac becomes infiltrated with pus-cells. The pus-cells are at first retained by the swollen hair, but ultimately burst through and form crusts between the cilia. If the process be allowed to continue, a contraction of a cicatricial character occurs in the outer root-sheath, so that the new hair can no longer push its way forward, but grows backward, thus assuming a hook-like form. Recovery from the blepharitis occurs only after all diseased hairs are extracted. In addition, however, it is imperative that the disease of the lachrymal passages should be completely cured.—*Klinische Monatsblatter*, No. 7, 1887.

OBSERVATIONS ON SOME VASO-CONSTRICTORS.—M. Trovati has made a series of experiments with the object of ascertaining the relative power of ergotine, hydrastin, and hamamelis as vaso-constrictors. When the blood contained 1–1,000 of ergotine the flow ceased in an hour. It diminished by a third in ten minutes, and by one-half in the same space of time, when it contained 2½ and 5 parts per 1,000, respectively. The extract of hydrastis reduced it by two-thirds at 2½ volumes per 1,000. The extract of hamamelis, in the proportion of 1–1,000, reduced the flow to one-half in ten minutes, and by two-thirds in the proportion of 2½ per 1,000. This test affords a good idea of the relative value of these drugs in the treatment of hemorrhage.—*Medical Press.*

A NEW SYMPTOM OF AORTIC ANEURISM.—Dalhee reports two cases of aneurism of the aorta in which an alleged new sign of the disease was observed. In one instance the disease was in the thoracic aorta, in which the ssame change, in the curve of the femoral pulse were observed as were described by Baltus in aneurism of the abdominal aorta. The peculiarity of the curve consisted in its low amplitude, and especially in a sharp hooklet resembling that met with in aortic insufficiency. This form of the curve is peculiar to the femoral artery. The symptom may prove of use in doubtful cases.—*Journal des Sciences Médicales de Lille.*

A SHOTGUN PRESCRIPTION.—Captain C. N. B. Macauley, Medical Corps, U.S.A., of Fort Gibson, Ind. Ter., writes: "A few days ago a civilian came to me for treatment for secondary syphilis. He had been under treatment by a physician in a large Michigan town. The following prescription, which I take the liberty of sending you, is copied, *verbatim et literatim*, from the original. The names marked * were hard to make out, but two of us decided that what is here written is correct:

℞. Iod. potassa	℥ ss.
Hydr. iod. rub	grs. x.
Aquæ pura	℥ viij.
* Fl. ext. poke root	℥ j.
" " stillingia	℥ j.
" " burdock	℥ iss.
" " gold seal	ʒ ij.
* " " podophylli pellets	ʒ j.
Spts	℥ iij.

Syrupi to fill one pint. M.
S. One teaspoonful three times daily.
(Signed) Dr. ——.

From the results of 'takin' more'n a pint of it,' as the patient said, I do not think Dr. —— was a very good shot, even with his medical shotgun. This is one of several specimens I have seen of curious prescriptions. The others were written or dictated by some self-styled 'local practitioners' down here in the Cherokee Nation. The physician who wrote the above prescription is practising in the Michigan town referred to."

ANTIPYRIN IN MEASLES.—Dr. F. W. Edwards, of Wilmot Flat, N. H., writes: "I have used antipyrin in a number of cases of measles where high fever, headache, and almost intolerable burning skin and thirst were the worst symptoms, and it has acted in every case like a charm, shortening the disease and stopping the intense soreness of the throat."

MEDICO-LEGAL ASPECT OF PREGNANCY ANTERIOR TO MARRIAGE.—Professor Brourdel says that Dr. Bonne was called one day to attend a woman who complained to her husband of spasms of pain in the region of the liver. The doctor noticing that the "spasms" resembled labor pains, asked and received permission to question the patient by herself. She confessed the truth to him. She had been pregnant for eight months, and married only six weeks. The doctor, rejoining the husband, told him the situation of things and urged him not to make a scene. The latter proved accommodating, and not only did not upbraid his wife, but condoned her acts in the presence of her family. Thinking the matter over, however, later, he wished a divorce, but was refused by the court on the ground that he had not made complaint instanter on discovering the facts set forth.—*St. Louis Medical and Surgical Journal.*

IT WAS AN OBSERVANT HOMŒOPATH, with a truly megalous head, who remarked: "Some trained nurses are trained nuisances." One sometimes feels that this training of nurses, like Dean Swift's beefsteak, is a little overdone.

AN ENGLISH TRIBUTE TO AMERICAN MEDICINE.—The American physicians are far ahead of us in this matter, especially in the field of gynecology. Where we have one gynecologist making a good income there are fifty in the States making pots of money. But the Englishwoman has not been educated to recognize her needs in this regard as her American sister has been.—*Hospital Gazette.*

"HÆC OLIM MEMINISSE JUVABIT."—A famous practitioner of many years' experience writes to the *Boston Medical and Surgical Journal* a story of one of his early experiences. It is a story that does credit to the doctors. He says: "In the early days of anæsthesia, I had quite a reputation as a giver of ether and chloroform. One day a distinguished surgical friend asked me to give the anæsthetic for him to a great and rich general, whom he had promised to castrate for malignant disease of the testis. I kept my appointment, and found the instruments arranged in order, the operating table, and the warrior eager to have the ill-behaved gland removed. Out of courtesy, I was asked 'to look at it.' I happened to know the clinical history of the patient, and soon satisfied myself that syphilis had claimed him for her own in a constitutional manner, and that trenchant steel was not what he most needed. I so told my brother doctor, who, being a noble, conscientious man, made an excuse to defer the ablation, put the son of Mars upon the appropriate treatment, and completely cured him. In the course of time, my 'gentle reminder' found its way to the hero's hand. Looking at it for some minutes, he said: 'What a —— outrage! That man just came to give me ether. It was found best by my surgeon to put off the operation, and Dr. M. didn't even give me the anæsthetic. He simply wasn't wanted, and went home. He must think I'm made of money, d—— him!'"

THE TIME IT TAKES TO THINK.—Men in all ages have been familiar with the fact that thought is habitually more active and more speedy in the case of some persons than of others. Whether in the exercise of the imaginative or the reasoning faculty, or in the action of that guiding purpose of life which we call the will, the general truth of this observation has been always evident. As we come to a higher stage of human development, with its corresponding increase of intelligence, it is not remarkable that the mind should seek to subject itself to a closer scrutiny, and to catalogue more exactly the results of its introspection. This has happened with regard to the question before us. In particular has the period which intervenes between the impact of impressions from without and the visible response of the will in muscular action or other mode of expression become of late years a subject of careful investigation. Since the first quarter of the present century, when the comparative speed of visual observation was chronicled in the case of the astronomers Bessel and Struve, the varying rate at which the mind responds to the numerous impulses which reach it from the outer world has been measured with some exactitude. Most of our readers are familiar with the term "reaction" period. They will recognize it as expressive of the whole interval between the action of a stimulus, of whatever kind, and the visible response of the individual affected by it. They will also perceive in the period of "reduced reaction" that interval shortened by the space of time allotted by experimental precision to the transit of purely sensory and motor impulses—the period, namely, which changes the one into the other, and represents in the mind the average time required to think and to will. Discoveries not now very recent have taught us that the ordinary duration of this period is, in the case of simple impressions, about one-tenth of a second, and that where the impression is rendered complex by affording the mind a choice of sources to which it may be referred, the time required is increased by about another tenth of a second. An equally interesting side of the subject, however, is that which exhibits the force of impressions as modifying the rapidity with which they are accepted, and, in familiar phrase, digested by the mental centres before they are visibly transformed into action. The rapidly energizing power of sudden fear, joy, hope, and desire is thus explained. So likewise the contrary effect of some of these emotions may be explained as being due to a stunning effect produced by the causes which give rise to them upon the mental centres. It is also manifest that the energy of the mental reaction must largely depend upon the reserve of force in those centres at the time of activity. They must not be overtaxed by prior stimulation and excessive use; if their response is to be a vigorous one, they must be well nourished and have seasonable rest. There is, therefore, even in these psychological minutiæ, a moral for the times—namely, that if we would preserve our mental efficiency amid the changing pressure of circumstances, we must by occasional recreation withdraw the mind from too continuous application.—*The Lancet.*

The Organization of a Firm of Patent-Medicine Manufacturers.—Professor Chandler says: "These firms of manufacturers of proprietary medicines, nine out of ten, live solely by the newspapers, and sometimes are admirably managed. I know some establishments in which there is a regular staff employed; I know something about them, because they try to bribe me to certify to the value of their concoctions. As I say, there is a regular staff. There is the literary man, who writes the letters, giving marvellous accounts of marvellous cures; there is the artist, who shows the patient before and after taking twenty-two bottles of the medicine; there is the poet, who composes poems upon the subject; there is the liar, who swears to what he knows isn't true, and the forger, who produces testimonials from his own imagination. Without exaggeration, I should say that nine out of ten of these proprietary medicines are frauds, pure and simple; the real business is advertising for dupes. The medical part of it is but a side-issue. I am pretty sure, if I were to pound up brick-bats, and spend $100,000 in offering it at a dollar an ounce, as a sure cure for some disease which cannot be cured, I should get back at least $110,000, thus giving me $10,000 for my trouble. Nine-tenths of the medicines sent out in this fashion have no more curative properties that brick-bat dust."

Temperature Sense.—Dr. Goldschneider has published the results of his experiments on the perception of temperature. It has been known for a long time that cold is more quickly perceived than heat. As a starting-point, he had first undertaken some direct measurements. He sought out portions of the surface of the body which were equally sensitive to heat and cold. These parts were then stimulated, as far as possible, with equal intensity, and the results were as follows, taken as a mean of about two thousand separate measurements: The reaction-time for cold as a stimulus is for the face, 13.5; for the arm, 18; for the abdomen, 22; and for the knee, 25 hundredths of a second. When an equally strong heat stimulus was applied, the numbers obtained were 19, 27, 62, and 79 hundredths of a second. The ratio of the reaction-times was found to be about the same when the stimuli were applied to such a nerve as the trigeminal, which goes straight to the brain and to a spinal nerve. The experiments on thermal stimulation were made by bringing a metallic button in contact with the skin and recording electrically the moment of contact; the resulting sensation was indicated by a Beiss key. The degree of heat and cold employed as a stimulus was selected so as to differ by equal amounts from the temperaure of the skin.—*The Dublin Journal of Medical Science*, December, 1887.

Calomel and Inunctions of Mercury in Syphilis.—At a recent meeting of the Imperial Royal Society of Physicians of Vienna, Professor Neumann discussed the value of the calomel treatment in syphilis. This method had been recommended in 1864 by Scarenzio, who stated that calomel was to be preferred in the treatment of syphilis before any other preparation, owing to the fact that it was first converted into sublimate and slowly absorbed, and that toxic symptoms were thus avoided. In modern times calomel had repeatedly been tried in Germany and Austria, and several observers, among whom might be named Professer Neisser, professed to have obtained admirable results with it. They said that a few injections were often sufficient to make the secondary symptoms of syphilis disappear. Professor Neumann had for some time past experimented with calomel, using a solution prepared according to the following formula: ℞. Calomelanos, sodii chloratis, āā 5.0 (five grammes); aq. destill., 50.0. M.—Sig. For injections. A Pravaz-syringeful, containing 0.10 (ten centigrammes) of calomel, to be injected at once. With this solution he had treated thirty-six patients suffering from macular, papular, pustular, and tubercular syphilides. The injections were made in the region of the buttocks, and not, as was formerly the case, into the affected parts, the "materia peccans," according to the expression of Lewin. The results which Professor Neumann had obtained were not, however, so favorable as those claimed by other authors. According to his observations more injections were required in order to produce the effect, and in one case he had even to make eighteen injections. To appreciate the value of an anti-syphilitic method of treatment, its action as a preventive had to be taken into account. Latterly the experiments which had already been recommended by Hutchinson, namely, to delay the outbreak of the syphilis, in spite of the presence of the primary affection, by means of inunction, had been taken up by several authors, and Professor Neumann, who had also tried this plan, found the appearance of the eruption could indeed be thus delayed, in one case even for one hundred and sixty days, but that no advantage was obtained by it; the course of the disease only became irregular, and, moreover, a greater number of inunctions were required than in other cases in order to cure the disease. As to injections of calomel, he observed that their effect was in this respect still less intense; and according to his own experience the calomel treatment was indeed a new, and in some cases valuable, method, but in general its effect was inferior to that of inunction.

"About the Size of a ——."—An English physician writes to the *Philadelphia Medical Times* a protest against the loose way in which physicians on both sides of the water describe the size of pathological objects: "Such time-honored comparisons as a 'fœtal head.' (I thought they varied a great deal) or 'a millet-seed' (I never saw a millet-seed, but I believe it to be about as big as a miliary tubercle), we cannot hope to get rid of before the millennium. But when it is a mere matter of length and breadth, could we not state the fact in inches or millimetres? I am moved to write to you by having been just now brought up by the statement that something or other was 'about the size of a dollar.' I was interested in this case up to that point, but I got lost then; the only dollar I ever saw was a tiny gold coin, 'about the size of a threepenny bit; I beg pardon, about fifteen millimetres in diameter. From the context, I think that the article mentioned must have been bigger than that, but I am not sure, and the statement bewilders me and destroys my interest in the case. Another time, I came across the statement that a tumor was 'about the size of a dough-nut.' Now as to a dough-nut my mind is blank; is it a nut that grows on a tree —a cocoa-nut, or a walnut, or a hazel-nut? or is it the other half?—'dough' suggests it is a kind of cake—a 'bath-bun,' or a 'tea-cake,' or, perchance, a cake 'about the size of a piece of chalk?' as the witness said in the famous trial. It is bad enough, Sirs, to have to learn two or three languages in order to keep ahead of the progress of medical science. Why should we, who speak the same language, throw these entirely unnecessary obstacles in each other's way? I hope you will lend your powerful influence to induce our American cousins to give their measurements in terms of some scale which can be mutually understood." The writer adds in a postscript: "P.S.—Since writing the above, a lady has told me that a 'dough-nut' is a kind of bun about the size of an orange, brown outside, jam inside, very good to eat, and 'they cost three halfpence.' Upon this I wish to ask: 1. Tangerine or Seville orange? 2. Is she right? 3. Granting 1 and 2, is this a satisfactory way of arriving at a pathological fact?"

THE NEW YORK PHYSICIANS' MUTUAL AID ASSOCIATION.—From the Nineteenth Annual Report of the New York Physicians' Mutual Aid Association we learn that the sum of $4,043 was paid to the heirs of deceased members, while the total of premiums paid by the insured was but $1,430 during the year ending November 1, 1887. The increase in the permanent fund during the year was $1,020.74, and in membership eighteen, thirty new members having been admitted, and twelve having died or been dropped for non-payment of dues.

CUBEB IN LARYNGEAL DIPHTHERIA.—Dr. Fedeli reports (*Revista de Ciencias Médicas de Barcelona*) a case of diphtheria with laryngeal complications, in a child, twelve years of age, which yielded readily to cubeb in four-grain doses hourly, after various other methods of treatment had been tried without effect.

THE NUMBER OF PHYSICIANS IN ITALY, according to official statistics published in 1887, was 17,586, not including the army and navy surgeons, whose number was upward of 1,000. There were also 11,873 apothecaries.

THE LONDON TRUSS SOCIETY recently held its eightieth annual meeting. This Society was founded in 1807, its object being, as its name implies, to supply the poor with trusses gratis. At the present time it gives away nearly 10,000 instruments yearly, and since its establishment it has provided over 430,000 sufferers from hernia with the necessary apparatus.

THE NEW YORK SKIN AND CANCER HOSPITAL.—According to the Fifth Annual Report of this institution, the number of cases of skin disease treated in the hospital during the year ending October 1, 1887, was 1,401, and of the various forms of cancer, 244. Of the latter, 112 were operated upon, and 96 were reported cured.

HYPNOTIC ANÆSTHESIA.—Dr. Pio Masetti performed an amputation of the cervix uteri, in the San Giacomo Hospital, of Rome, upon a patient in a hypnotic condition. The woman gave no evidence of suffering any pain, and lay perfectly still during the operation.

RESECTION OF TUBERCULOUS JOINTS AND GENERAL TUBERCULOSIS.—Dr. T. Wartmann has collected from various sources the statistics of 837 cases of resection for tubercular joint disease. Of this number, 225 ended fatally. Among these deaths were 26 from acute miliary tuberculosis, the outbreak of which the author was inclined to refer to the operation as its exciting cause.

OXYPROPRYLENDIISOAMYLAMINE.—This is a new alkaloid prepared by synthesis. In moderate doses it is said to be a heart tonic, and doubtless the rapid repetition of the word itself would be found a very useful gymnastic exercise in cases of stuttering.

BUFFALO-POX.—In India the experiment has been made of cultivating bovine virus through young buffaloes, and is said to have been very satisfactory.

A BACTERIOLOGICAL INSTITUTE IN BARCELONA.—A rich merchant of Barcelona, Don Pablo Despau by name, recently gave a large sum to establish an institution for the treatment of rabies after Pasteur's method. The city authorities added to this another large amount on the condition that provision be made for histological and bacteriological research. Dr. Ferrán, of cholera-inoculation fame, was appointed director of the new institute.

THE FRENCH ASSOCIATION FOR THE ADVANCEMENT OF SCIENCE will hold its congress for the year 1889 in the city of Paris.

ABORTIVE TREATMENT OF FURUNCLES.—Dr. Jorissenne treats commencing furuncles by an ointment composed of 1 part of red oxide of mercury to 100 parts of lanoline, and claims that suppuration is prevented when the application is made early. The same treatment is of service, he says, in acne.

YELLOW-FEVER INOCULATIONS.—The claims made by the followers of Freire that yellow-fever inoculations afford an absolute protection against the disease, have, it is said, been abandoned. It is now held that they merely render a subsequent attack of the disease milder than it would have been without previous inoculation. Among inoculated persons the mortality has been reduced to one in a thousand.

THE HYPNOTIC ACTION OF ANTIPYRIN.—Dr. J. Blake White, of this city, writes: "In THE MEDICAL RECORD for February 4th my attention was arrested by a short paragraph in which Dr. Stubbert, of Bloomfield, N. J., claims to be the first to have called attention to the hypnotic effects of antipyrin. The doctor presumably overlooked my article on 'Antipyrin as an Analgesic' in THE MEDICAL RECORD, September 11, 1886, in which its benefit in neuralgic affections about the head and face was pointed out, and a portion which relates to its hypnotic effects, permit me to quote: 'The grateful relief from headache usually ensues within half an hour after the drug is taken. A sense of *drowsiness* ordinarily supervenes, followed by a brief but sufficient slumber, and the patient awakens quite relieved,' etc. Before my article was written I recognized the hypnotic effects of antipyrin, and had prescribed it in cases of insomnia with good effect. While writing on the subject, permit me to add my testimony to its value as an analgesic and therapeutic measure in acute rheumatism, either by the stomach or administered hypodermically as advised by Professor Sée."

LONGEVITY IN JAPAN.—According to the census of January 1, 1887, the population of Japan numbers 38,507,177. There are 1,086,001 between seventy and eighty years of age; 247,055 between eighty and ninety; 12,220 between ninety and one hundred, and 97 over one hundred years of age. There are two women one hundred and nine years of age, and one who has attained the venerable age of one hundred and eleven. Of those over one hundred years of age, 73 are women, and but 24 men.

Original Articles.

XERODERMA PIGMENTOSUM AND ITS RELATION TO MALIGNANT NEW-GROWTHS OF THE SKIN.[1]

By R. W. TAYLOR, M.D.,

SURGEON TO CHARITY HOSPITAL, NEW YORK.

In the year 1870 Hebra and Kaposi[2] published in their text-book a description of a disease of the skin peculiar to early life, presenting polymorphous lesions and a complexity of symptoms, chronic and unending in its course, indelible in its disfigurements, prone even from its benign lesions to impair or destroy vision, to more or less disfigure and destroy the ears, nose, and mouth, and by its malignant new-growths to lead to death. This truly wonderful but terrible disease Hebra and Kaposi called xeroderma. Their description was based on four cases, two of which Geber,[3] in 1874, published in greater detail under the title, "A Rare Form of Nævus," using the latter term as applied by some authors to any congenital or very early disfigurement of the skin. In 1877 I read before the American Dermatological Association a paper containing the histories of seven cases of this disease, which had been under my continuous observation for a number of years. At this meeting Dr. Heitzmann related a case.

In 1878 I read a second paper, including the observations made since the former paper was read, and for the reason that, although my paper was complete as regards the clinical history of the mild lesions, I preferred, before publishing, to watch the cases over a long period of years in order to study both their tendency to malignant new-growths and the course of the benign growths. This paper, therefore, is based on seven cases observed during a period of fourteen years. In 1878 Dr. Duhring[4] also reported a case.

In the year 1882 Kaposi[5] published a paper on this subject, in which he called the disease xeroderma pigmentosum, not thinking that the provisional name given to the disease by myself, *angioma pigmentosum et atrophicum*, correct, but taking the adjective pigmentosum as a suffix to xeroderma.

In 1883 Neisser[6] published a paper based on two personal cases, and seven by Rüder, one of which should be dropped, in which he called it *liodermia essentialis cum melanosi et telangiectasia.* Later in 1883 Vidal's[7] paper appeared, in which he called the disease *la dermatose de Kaposi;* such was his enthusiasm for his Teutonic colleague. In the year 1884 Pick[8] published a noteworthy paper on this subject, in which it is evident that he has a clear and accurate knowledge of the disease, which he calls *melanosis lenticularis progressiva.* In the same year Radcliffe Crocker[9] published a paper containing the histories of three cases, the only ones seen in England, in which he proposed the name *atropho-derma pigmentosum.* In 1885 Kaposi[1] published the recent details of his ninth case, including those of Hebra and Geber. In the same year Dr. J. C. White[2] published the histories of two cases observed in Boston, and Dubois-Havenith[3] the history of one case. This constitutes the literature of the subject from ten observers, including forty-one cases, one of which is so imperfect that it must be rejected, leaving forty cases as the basis from which to draw our knowledge of this singular disease. Though the term "xeroderma pigmentosum" is far from perfect, it has the advantage over others of brevity, and will probably come to be accepted generally.

The histories of my cases are as follows:

Case I.—D. M——, born in Columbus, Ga., came under my observation, April, 1874, when three and a half years of age. Her parents and family relations, who were Hebrews, were free from all diseases, particularly affections of the skin. The father and mother were both of dark complexion. D——, a brunette also, was an only child, well nourished and in all respects healthy until she was seven months old, when her mother noticed two bright-red spots, one under each eye, which she thought were the result of sunburn from the carelessness of the nurse. Although numerous remedies were applied, the spots increased rapidly, and within six months the whole face was invaded. The general appearance was then described as a pinkish redness of the skin, with numerous small brown spots. Within the next two years the affection still increased at the periphery of the patch, until, when seen by me, in its third year, the whole face and part of the neck were involved. The following conditions were then noted: The face presented a mottled appearance, the general tint or background was of a pinkish color, the skin having a glazed, stretched look. Here and there, particularly under the eyes and about the nose, were in all about one dozen whitish, pearly-looking, distinctly atrophied patches, on a few of which were numerous small brown spots; in short, freckles. Besides these, scattered irregularly over these atrophied spots, but being rather more abundant near and between the white spots, were a considerable number of minute, slightly elevated and scaling specks of a bright-red color and irregular in shape, which, when examined with a powerful glass, were seen to be composed of groups of minute blood-vessels. In rather greater numbers than these red spots, and more extensively, but more irregularly, distributed over the whole face were spots varying in color from the light brown of ordinary freckles to a blackish brown. They were neither elevated nor depressed, of various shapes, all, however, irregular—some linear, others oval, others, again, angular. Their surfaces were, as a rule, smooth; on some, very minute, dirty scales were seen, while in the centre of a few an enlarged follicular opening was present. These openings of both perspiratory and sebaceous glands were much enlarged, and the usual minute lines of motion of the skin were much deeper, and could be seen to divide up the whole surface into little irregular patches. The minute hairs of the face were still present. The want of elasticity of the skin was well shown at the eyes, over the nose and at the mouth, and its general condition may be said to have resembled that following an extensive, but quite superficial, burn, or the reparative stage of eczema, when the scales and crusts have fallen off and we still have slight hyperæmia. To the touch the sensation was somewhat similar to that felt when passing the fingers over parchment or integument glazed with a coating of flexible collodion. There was no infiltration proper, but rather a condensation of the skin, or a fusion of it with the uppermost layers of the connective tissue. It could be picked up in most places, but the whitish spots were firm, and seemed rather more bound down than the rest. These spots require especial description. They were of various shapes and sizes, from a diameter of one quarter to that of one inch, having no perceptible margin, but merging imperceptibly into the surrounding pinkish integument. They presented a more glazed appearance and corresponding feel than did the other parts, were not scaly, and upon their surfaces no follicular openings were to be seen. When pinched, always with difficulty, between the fingers, it became evident that they were composed of very much atrophied skin, which was firmly connected with the softer tissues underneath. Over some of these patches were a few of the red spots mentioned before, and a few of the black or brown ones.

It remains to mention the condition of the skin under the jaw and upon the neck. Here the affection was of most recent development, and it ended by an abrupt semilunar margin. The appearance was that of a very superficial hyperæmia, without, however, the usual sensation of heat, the color being of a pinkish-red glazed tint, a little deeper than that of the face. There were here and there the red specks, but no atrophic patches, and very few light-brown pigmentations. There was little or no scaling, and as the finger-tip passed from the morbid to the healthy parts no marginal ridge was felt, and the sensation conveyed was that of a dry, smooth surface to that of the normal softness of the skin. The glazed, dry sensation was explained by the almost total absence of the normal secretions. The region in which the sebaceous glands were most numerous was the one most radically involved in atrophy. The integument of the back of the neck, from the hairy margin to that at which the clothing ends, was similarly affected to the face, presenting a small number of red spots and pigmentations, and much cicatrization in small patches. There were irregular-shaped scars with branching processes, others depressed and having the appearance as if punched out. These resulted from abscesses, beginning in the sebaceous follicles, which had occurred from time to time during the past year. Similar lesions had developed about the face, and had caused minute, speck-like scars. The affection stopped abruptly at the frontal and occipital hairy margins.

The hands also showed marked abnormalities. The general appearance was that of a rather less supple skin, with myriads of pigment-spots. There was, moreover, more of the normal feeling in these parts, very little atrophy, particularly over a few of the heads of the metacarpal bones. The parts involved were the backs and borders of the fingers and hands, as far as the wrists. There was less redness apparent, less general change in the structure of the skin. In fact, the only way in which I can describe its structure on the hands is by saying that it was perhaps rather more condensed than normal. By far the greater portion was covered with small, lentil-sized, irregular-shaped spots, varying in color from a light brown to a blackish brown, having, however, a sharply defined border. Between these, and, of course, occupying a relatively much smaller extent of surface, was the light-pinkish background of the integument. In short, the hands, to casual observation, looked as if nearly covered with lentigines or freckles. At the wrist there was no defined margin of the abnormal condition, but rather an imperceptible merging of normal with abnormal integument. Ending in a like manner at the sides of the fingers and hands, the affection wholly spared the palms and matrix and bed of the nails. Heat, burning, and itching were absent. There was, of course, a feeling of stiffness about the eyes, face, and mouth especially, but it caused no complaint.

As to the conjunctivæ, little need be said, except that they were slightly hyperæmic.

The parents of the three following children who are afflicted with this disease are of the Hebrew race, and had never suffered from any sickness or skin disease. Their complexion is dark and their hair black. The husband is fifty years of age and the mother forty-four. They have been married twenty-four years and have ten living children. They are first cousins, their mothers being sisters. Of these ten children, three have this skin affection, namely, the second, the sixth, and the seventh, all of them girls. The sister of the mother of these children was married to a maternal second cousin, and they, too, are the healthy parents of five children, two of whom, namely, the second and fifth, were afflicted in the same manner as their cousins. The second child was a boy, the fifth a girl. Both of these children were, like their parents, of dark complexion.

CASE II. (in 1877).—A. B——, aged thirteen, brunette, was rather sickly in early infancy. She was the second child and of frail build, but free from all skin affections until fourteen months old, when her mother observed little red stains under the eyes. These soon became a continuous patch, and in six months the whole face was invaded. At first the affection consisted in a pinkish redness of the skin, upon which little spots of deeper red appeared quite thickly all over the face, and were called by a physician measles. Gradually these red spots became of a light, then of a dark, brown. These spots of a yellowish and of a blackish brown were very copious upon the face and neck, and they appeared on the cheek following the prodromal hyperæmia. In all of these parts they increased in number. During the second year atrophy began on the forehead and face, leaving patches of thin, pinkish skin, upon which the pigmentations were very few. While this process was taking place many of the dark spots elsewhere underwent absorption (Fig. 1). While the face was thus profoundly and extensively affected by atrophy, the skin of the extremities and neck was only disorganized in small spots and in less degree. The pigmented spots varied in size from a pin-head to a pea, being larger on the face than on the hands.

When first seen by me, in 1874, the girl was ten years of age, of fine health, and of bright intellect. The integument of the forehead was so thin that the vessels were readily seen, and that of the nose in a similar condition, and bound down to the cartilage. A similar state existed on the cheeks and lips, which were much deformed and everted. Over the right eye, involving almost the whole ciliary legion, is an ulcer, situated nearly in the axis of the brow, which extends almost to the bone and has destroyed almost all of the brow (Fig. 2). It has thick, raw, granulated edges, and a raw, red base. At the outer margin of the lower lid is a fungus-like tubercle. Under the lid there was much cicatricial tissue, and, as a result, ectropion. In fact, this eye is, under all circumstances, nearly unprotected. The lids of the left eye were also cicatricial, and their conjunctiva and that of the eye was intensely hyperæmic, that of the lids having a raw appearance. Ectropion existed on this side also. The right cornea is opaque in nearly its whole extent, and to it, from the inner side, large, straight vessels converge, the same feature being seen on the left side. There are two very vascular tubercular elevations on the right cheek, near the ala nasi, separated by a raw fissure. The larger one is of the size of a nutmeg, the smaller of that of a pea. Under the lower lip, near the right angle, are two similar smaller tubercles. The ears are stiff and hard, owing to the atrophic contraction. In the spots where earrings have passed, the lobule is shrivelled and ulcerated. The deep vessels can be seen through the atrophied skin, running over the upper part of the ears. The affection seemed to spare the deep part of these organs, since hearing was perfect. There have been quite well-marked changes in the structure of the scalp. In places it is distinctly atrophied, and everywhere the hairs are thin and dry. There were many small follicular abscesses, and from the whole surface there is much scaling, with here and there plates of sebaceous matter. Scattered sparsely over the whole scalp were small pigmented spots of light brown. There were many of these scattered over the face; being less abundant in the most atrophied places, on some wholly absent, so that this child presented less of them on the face than any of the others. These same spots extended to the level of the third rib, and were extremely copious over the backs of the hands, fingers, arms, and forearms, to the shoulder, being much more abundant on the extensor than on the flexor surfaces. On the legs, mostly on the extensor aspects, also on the flexor, spots of a lighter color—indeed, I may call them freckles—have lately appeared; some have been observed on the upper parts of the feet. There were seen, but in much less profusion than the brown ones, small red, vascular spots of varying shapes, irregular, some linear, generally very small indeed. These are most numerous on the face and neck, less so on the other affected parts. The submaxillary and cervical ganglia were much enlarged, but are not painful. The sensation felt by passing the finger over the face is that of abnormal smoothness, similar to that imparted by parchment, and a feeling of preternatural heat. The follicular openings were nearly all destroyed on the face. Small hairs were seen sparsely scattered over this whole region, while the eyebrows and eyelashes were nearly all destroyed. The normal surface markings were much enlarged. A peculiar immobility of expression was present.

The atrophic process began in the second year of the disease. From that time until now, the thirteenth year of the affection, it has continued, involving various parts at short or long intervals, running an uncertain course, sometimes active, at others passive, exacerbations and remissions alternating. Thus it is that in some cases the atrophy is greater than in others. It was an essentially erratic process, not extending peripherally, but, I may say, at hap-hazard, now here, now there, never being of acute course. In addition to this atrophy there are evidences of further and severe changes, particularly at the junction of the skin with the mucous membranes and upon the ears and nose. Superficially elevated tumors at the angles of the eyes and mouth developed when the child was six or seven years of age. Upon the atrophied patches near mucous tissues small elevations of epidermal structure, and much pigmented, could be seen. They resemble at first keratosis senilis. Some of these attained but a slight elevation, and then underwent spontaneous involution. Others grew in height and breadth. The large tubercles of the cheek appeared within three or four years, having their origin in the same dark spots. The course of the swellings of the lobules has been toward loss of tissue, with marked deformity. Then, again, it has been noted by the parents that the brown spots were not always permanent, though, as a rule, there were many, having become almost black, underwent involution. On the atrophic patches the red spots appeared, formed dark ones, which remained for a time and then disappeared. During this process the atrophic changes were slowly going on. On the hands the atrophy was greatest over bony prominences. Intelligent medication, extending over many years, was ineffective. The mucous membranes of her lips were the seat of the brown and red spots. The nails were unaffected. During hot and cold weather this patient suffered much from congestion of the affected part. This patient was more severely afflicted than any of the others.

During the following six years the most notable feature of the case was the increase in the atrophic changes and the greater development of the supraorbital tumor, which extended to the temple. The new-growth had a fungating surface, not very vascular, with everted edges, and consisted of segments. It was removed by Drs. Gruening and Gerster, who saw the case in consultation. The new-growth extended to the bone, and was thoroughly scraped out. The eyeball was removed several months later. In 1886 ectropion of left upper eyelid necessitated blepharoplasty, which was performed by Dr. Gerster with a successful result. Microscopic examination showed epithelioma, whereas tumors removed in 1877 were myxo-angiomatous in nature.

CASE III.—T. B.——, the fifth child, and the third and last one thus affected, was, in 1876, seven years old, healthy, well nourished, intelligent, and of dark complexion. The affection began under the eyes, as red spots, when the child was less than a year old, and has persisted ever since. She is of somewhat lighter appearance than her sister S——, and presents only pigmentation, with small atrophic patches (Fig. 3). It is only necessary to briefly state her present appearance. There are over the whole face many dark spots, some of large size; among these are a corresponding number of vascular points. The neck, hands, and forearms are also very dark, but in all parts the tint is slightly lighter than in the sister whose history precedes this. There are several atrophic patches about the nose and cheeks, but none on the lids. A well-marked hyperæmia of the conjunctiva produced a moderate photophobia. The ears are stiff and pigmented, but not ulcerated. There is an absence in this case of all epithelial hypertrophy; indeed, the affection may be summed up as diffuse pigmentation, with a small amount of atrophy of the skin. There is the same amount of seborrhœa in the scalp—the hairs of which are dark—and the face has the same apparent elevation of temperature as felt in the other cases. The general features of the pigmented spots, and of the skin thus freckled, are the same as in the preceding case. The submaxillary and cervical ganglia were perceptibly enlarged. There were a few pigmented spots on the lips. Though there are atrophic patches on the face, they are of slight extent, and do not produce much deformity.

During the following six years the cornea became covered with pannous growths, which were removed by Drs. Gruening and Gerster in 1883. The girl also suffered from inveterate pharyngo-nasal catarrh, with chronic otitis and considerable impairment of hearing.

CASE IV.—S. B——, the sixth child, and the second one affected, was, in 1876, eight years of age, and, like her sister, enjoyed good health. She is rather stouter than her sister A——, and has always been well until within six months, when she suffered from rheumatism, which has left no perceptible lesion. Viewed at a short distance in a subdued light she might be taken for a colored child, so profusely and deeply pigmented is she. When born, this child was of very dark complexion, and from this circumstance the parents feared that she would be affected like her elder sister. These fears were realized, since the red spots appeared under the eyes before she was a year old. They soon formed a large patch, and in less than a year the whole face was invaded. When two years old this whole region was covered with the pigmented spots or freckles, in no way differing from those of her sister and of the other cases. From that time until now, being a period of seven years, the morbid process has gone on in the same manner, but with less intensity in certain respects than in her sister. The pigmentation has been at times, as it is now, very deep, and again it would become lighter. The mother observed that these spots came out in crops, which were not always developed as rapidly as in others. In hot weather they became darker, and appeared more quickly than in cold. The present condition of this child is briefly as follows: The principal change observable on the face is the dark, copious pigmentation of nearly the whole surface. The trouble stops quite abruptly at the margin of the scalp, upon which are only a few spots and slight seborrhœa. The absence of large patches of atrophy is noticeable in this case, and the only places where it appears in small, irregularly shaped patches, and without sharp margins, are at the eyes, nose, and mouth. In fact, the process has not been so severe as in the other cases. There is slight ectropion, owing to the condition of the lids. On the right eye, springing from the inner side and overlapping the corner to the extent of half a line, is a little, rather square-shaped, pinkish elevation, to which a number of large, straight vessels run directly from the inner canthus, and over its surface some minute capillaries ramify. This structure, seemingly of epidermal formation, has a diameter of about one-twelfth of an inch and an elevation of one-third of a line. Both surfaces of the conjunctiva are markedly hyperæmic. Beginning at each inner canthus, at the root of the nose, is, on each side, a line of tubercles, which, diverging with the expanding alæ nasi, form a **V**-shape figure with the apex upward. These tubercles, in all about sixteen in number, varied in size from small points to the size of half a pea (Fig. 4). They were of a dirty black color, some covered with a crust, upon the removal of which a raw, bleeding, and slightly fungous surface was seen, others being a little scaly. Besides these there are irregularly placed over the whole face numerous small similar tumors. In the early stage of these lesions they were simply pigmented and scaly spots like keratosis senilis; later they reached a diameter of nearly half an inch, having a slightly adherent crust. The largest tubercle on the face is under the left eye, occupying the greater portion of the lower lid. Similar pigmentation to that of the other cases was present upon the neck, very much worse, however, on the back of it, reaching as far down as the third rib. Intermingled among them were many vascular spots slightly raised, sometimes scaly. Such spots were seen also on the extensor surfaces of the hands, forearms, and ears. A few of them were present on the exposed surfaces of the lips. She suffered from photophobia in a mild degree. There was slight immobility of expression of the features. The cervical and submaxillary ganglia were distinctly felt. The pigmentation in this case had varied in intensity at different times, and had also appeared in crops. This child had suffered from measles, with no perceptible influence upon the chronic skin affection. In this case these dermal changes had lasted seven years. Within a year of its development the whole face was invaded, and some part of the upper extremities; after that it ran an uncertain course, and was complicated at its third or fourth year with the formation of the epithelial tumors. The feel of the skin is rather rougher than normal, yet its suppleness is not much impaired.

Most of the tumors on the face withered and fell off, and some were removed by scraping. Toward 1882 a tumor formed on the left temporal region, which, in 1883, had attained the size of a hazel-nut. It was removed by scraping by Dr. Gerster, without much bleeding. The wound healed rapidly. The structure of the tumor was friable, and it was found to be a granuloma.

The children whose histories follow were cousins of the three foregoing cases. The first, a boy, E——, was the second child, his elder brother having been healthy. Following him in order of birth were three children, two girls and a boy, who were always perfectly healthy, while the sixth, a girl, was affected similarly to her brother and her cousins.

Case V.—E. W—— was, in 1876, the only male subject who had then been known to suffer with this skin affection. He was, as an infant, healthy, and of average strong build and dark complexion. He was affected with the same form of red spots under the eyes as have been described. They appeared when the child was about a year old and ran a precisely similar course to that observed in the other cases. In a year the whole face from the hairy margin was greatly pigmented, also the neck as far as the third rib. The hands, including fingers, the arms, and the forearms were the seat of dark, copious pigmentation. There was much atrophy about the face, particularly about the nose, eyes, and cheek. Ectropion and its resulting photophobia were very severe. There were also pigmented epithelial tubercles about the nose. No change in the general health of the boy was induced (Fig. 5). When he was seven years of age he was attacked with mumps, which ran a severe course and were followed by an abscess. This was opened, and, though properly treated, the wound never healed. The edges became thickened and fungoid, the general appearance being that of an epitheliomatous tumor. From the integument the deeper parts became infiltrated, even to the deep arteries. Ulceration occurred in the morbid tissue to such an extent that an artery was eroded, and in spite of careful treatment the hemorrhage became uncontrollable and death ensued.

Case VI.—H. W——, the sister of this boy, and the sixth child, the only one of the five afflicted cousins who has light hair, was, in 1877, nearly four years of age. She enjoyed good health. She became affected with the typical red spots under the eyes before she was six months old. The parents took this child immediately to the Hot Springs of Arkansas, where she received baths and internal medication. The effect was discouraging, since the erythema was more rapid in its course and the appearance of the pigmentations more prompt and upon a greater area than in the brother's case (Fig. 6). The appearances were like those of the other children. The face of the child was very dark, nearly covered with the blackish-brown spots, and among them a less number of smaller red ones. The neck also was pigmented. The extensor surfaces of the hands and forearms also presented a piebald appearance. About the nose and cheeks there are several atrophic patches, thin and not much spotted. They had a parchment-like feel. The conjunctivæ were very hyperæmic, and upon the sclerotic were numerous large, straight vessels. The ears were stiff and pigmented. Several minute brown spots were seen on the lips. The scalp was nearly normal. The heat of skin already spoken of and a slight roughness of the integument of the arms were felt. The ganglia were swollen. In all minor features this case resembled the others. The child died by drowning when eight years of age.

Case VII.—L. S——, a brunette, the eldest child among six, of healthy Hebrew parents, was well nourished and well until she was six months old, when her mother noticed two large red spots under the eyes, which she thought were caused by exposure to the sun. From this time until seen by me, in 1876, when she was twelve years of age, the affection had continued. The girl was well built, of normal stature, and good health. The parts affected were the face, neck, and upper and lower extremities. The face was, as a whole, of a shining, whitish tint, with here and there sparsely scattered red and dark brown spots. The whole surface of the forehead, extending into the scalp, was composed of tightly drawn, much thinned, whitened skin, which was with difficulty pinched up into folds, and so closely drawn to the bones that all of the raisings, depressions, and sutures could be noted. In the scalp there were many pea-sized, pigmented spots of dark-brown color, with numerous small follicular abscesses, besides which there were small whitish cicatrices, the results of previous lesions. There were a number of irregularly shaped, dark brown spots, in all perhaps two dozen, scattered over the atrophied pigmented skin of the forehead. There were but few eyebrows, and the upper eyelids were atrophied, shrivelled, and drawn up. The general condition of the skin of the nose and face was that of atrophy. The lower lids were similarly shrunken and drawn down, leaving the eyes uncovered, the corneæ opaque. The nasal apertures were much smaller than normal, wholly immobile, and the margins of the alæ nasi were markedly thinned. The tightening about the mouth was such that the aperture was simply a straight slit. The mucous membrane of the lips was much discolored. The same atrophied state existed on both ears; but on the left one, springing from the outer and inferior surface of the lobule, was a distinctly pedunculated tumor of the size of a nutmeg, having a fungoid surface. There was a similar but rather more angular and larger tumor on the right cheek, stretching from near the ala nasi to the angle of the mouth, being less prominent, flatter, and rather more sessile. At its inferior border were three similar smaller tumors. These new-growths began when the child was five years of age. The lobule of the right ear was very much shrunken. Scattered over the backs of each hand were irregularly outlined, atrophic, whitish patches, a few of which extended to the dorsum of the fingers. Upon the atrophied surface of the face were scattered, in all, about three dozen light, to a very dark brown, pin-head to pea-sized spots, not raised or depressed, without any lustre, and contrasting very strongly with the shining white background. These spots were less copious on the cheeks, and more so at the periphery of the face. Besides these were a rather less number of bright red-spots, of about one-half to one line in diameter, very little raised, and composed of dilated capillary vessels. On the neck the skin was more easily pinched up, but much more profusely mottled with brown spots on the arms as far as the shoulders and forearms. In these places the skin was rather dry, and slightly scaly and moderately atrophic. On the skin of the face the natural furrows were very distinct. Upon the nose and cheeks the follicles had been destroyed.

During the year 1878 the tumors at the angle of the mouth and nose became much enlarged and ulcerated. The girl died of marasmus in the month of January of the following year. The nature of the growth I found to be epitheliomatous.

In these seven cases all of the clinical features of the disease are clearly portrayed. The various lesions presented admit of sharp division for descriptive purposes. The disease—xeroderma pigmentosum—itself consists in the telangiectases, the pigmentations, and the atrophic changes, all of which have the most intimate pathological relations. Superadded to these polymorphous lesions there are sequelæ, or new-growths, which are at first of a benign nature, and may thus remain, or they may degenerate into malignant growths. We shall first study the course of the disease itself, and then consider its resulting new-growths.

Of my seven cases the disease began, according to reliable testimony, in six at about the sixth or seventh month, and in one case at the fourteenth month. It is much to be regretted that several observers have failed to learn or to state the date of invasion. In twenty-six of the recorded cases, including my own, given in brief in the table which I present, it is stated that it began in between the third month and the end of the first year in ten cases. and between the first and second year in fourteen cases. There is inherent evidence in several other cases of very early evolution. In marked contrast to these twenty-three cases are those cases reported by Kaposi, Heitzmann, and Vidal, in which the date of the appearance of the disease is respectively stated at sixteen and nine and more years. Dates of evolution are not given by Kaposi in one case; Rüder, quoted by Neisser, in six; and Vidal in three cases. While I am not in a position to deny that these cases of late evolution are those of xeroderma pigmentosum proper, I must say that I am very sceptical about them, seeing that they are so exceptional in their course. It should be distinctly borne in mind that the coincidence of epitheliomatous and other malignant growths upon the faces of persons, the subjects of deep or light pigmentation, does not of necessity constitute xeroderma pigmentosum. The weight of evidence, therefore, places this disease as one of very early childhood.

The invasion of the disease is very constant, beginning about the face or under the eyes as a well-marked, smooth, superficial erythema, which is often regarded by the parents as the result of sunburn. With the exception of this blemish, there is no impairment of health; indeed, the fact of the good health of most of the children is well attested. The erythematous patches extend, coalesce, and gradually creep over the face and neck, usually stopping at about the third rib by an abrupt margin. This condition of the face, neck, and trunk is of variable duration—from one to several months—during which the erythema may become less red. As this prodromal hyperæmia disappears, pigmented spots and red ones, or telangiectases, make their appearance, scattered irregularly over the affected regions. The pigmentations are at first of a light-brown, and may become of a blackish-brown, and even black color. They vary in size from a pin's head to a lentil, and usually are not much, if at all, elevated, and of very irregular shapes. Scattered among them with great irregularity, but less numerous, are the red or telangiectasic spots, which are smaller, rather more salient, and of irregular outline. By a strong glass a congeries of capillaries can be made out. In most cases thorough pigmentation of the face and neck takes place in about six months. Upon the hands there is not such a marked prodromal erythema as upon the face, and in some cases there was no evidence of its presence. With the evolution of these lesions there are no marked local subjective symptoms. If a case is carefully studied, and frequently observed in its early years, it will be very often plain to the eye that the pigmented spots follow exactly upon the site of a pre-existing red spot, and the conclusion will be obvious that the red lesion was the forerunner, and that its pigmented fellow was the sequela. This I have seen to take place time and again. Very often pigmented spots appeared where the red one was only visible by means of a glass. The pathological relationship, therefore, between the red and the pigmented spots is, to my mind, very clear. My friends Dr. Duhring and Dr. J. C. White deny this relationship, but I think that, had their observations been made upon very young children in whom the disease was active, and not on older ones, and had they extended over longer periods of time, they would be of my belief. Later on I will show that the microscope demonstrates the intimate relationship claimed. The further course of these two orders of lesions is well shown in the histories of the cases. They are erratic, they come and they go; they have periods of exacerbation and of remission, but their hold is never lost. If one disappears it is soon replaced by another, or by several. Thus, as the child grows older, its disfigurement becomes more or less rapidly worse, the disease relentlessly persisting. There is no record of a case in which anything like amelioration in its course was observed. A very few children escape with the disfiguring pigmentations, and perhaps slight atrophy; but even these are either attacked later on by severer lesions, or the milder ones remain indelible for life. The period of activity of the pigmented spots and telangiectases is greatest in the very early years and during childhood. After the fifteenth or sixteenth year they may appear and disappear, but rarely in such profusion as in the early years.

These two orders of lesions—the telangiectases and pigmentations—are peculiar to what we may call the stage of hypertrophy of xeroderma pigmentosum. Disfiguring as they are, we find that in every case—in some in a mild and in others in a severe form—atrophic changes are soon superadded. In the majority of cases atrophy begins about the end of the first year of the existence of the morbid changes, but it may occur at any subsequent period. Its course is subject to marked exacerbations and remissions, and though it occurs on both sides of the body it is not usually symmetrical. In some cases it progresses and produces hideous deformities by reason of the size and situation of the patches; in others, again, it is limited in extent and not strikingly observable. Upon the face this form of atrophy reduces the skin to the thinness of parchment, and destroys nearly all of the follicles. Such atrophic patches are usually traversed by minute lines, and frequently so transparent are they that the vessels can be seen beneath. Upon the hands and arms, and feet and legs, atrophy is not usually as well marked as upon the face, and it occurs mostly on parts subjected to tension, such as over the knuckles. If an atrophic patch of the skin of the face is attentively watched for a long period, it will be seen that there is a constant evolution and involution of the telangiectasic spots, which are here sometimes followed by pigmentations. The atrophy of the skin takes place in proportion to the growth and atrophy of these minute vessels. and always where the atrophy of the skin is active close observation will show this rapid development of the red spots. This process seems to go on until all of the vessels of the part have undergone increase and decay; in fact, until no more are left, or until the skin is reduced to such a dense fibrous condition that they can luxuriate in it no longer. Due undoubtedly to the excessive vascularity and exposed position of the parts, atrophic changes are prone to occur upon the forehead, also on the scalp, about the eyes, nose, mouth, and ears. As a result, besides the disfigurement, ectropion occurs, with its train of bad symptoms. and incomplete stenosis of the nasal and oral apertures and deformities of the ears are produced. It is an interesting fact that when the atrophic process is at an end, no further pigmentation takes place, and a smooth, white, mother-of-pearl surface is left.

In almost all cases, particularly in those in which the pigmentations are deep and extensive, hypertrophic changes take place, very often coincidently with the atrophic processes. We find in the course of xeroderma pigmentosum epithelial new-growths. In their simplest and most rudimentary form these consist of plaques or spots, or thickened pigmented epidermal cells, resembling keratosis senilis. This may be the full development of the hyperplastic process in a given case, or it may be the starting-point of larger growths. While the atrophic process is to be dreaded for its terrible disfigurements, these at first seemingly simple and harmless growths are often more terrible in their effects, since their development produces the leaven upon which malignancy may later on be ingrafted. These are border-line lesions between benign and malignant new-formations. These keratosic patches may long remain as such, or they may be cast off and re-formed, and they may disappear. But about the face, particularly at the junctions of the skin with the mucous membranes on the cheeks, chin, and ears, their tendency is to become larger. They soon form sessile or pedunculated, more or less elevated tumors, whose surface after the shedding of their pigmented epidermal covering may in general be termed fungating. At first they are of a deep-red, or purple-blue color, soft and compressible, and remind one of erectile tumors. They frequently become pale, less vascular, and so brittle and friable that they fall off, leaving sometimes a surface which heals spontaneously, or an ulcer which may be very intractable, which may extend in depth and breadth, and frequently are surrounded by thickened and everted edges, which may become the seat of malignant degeneration.

Thus far in the hyperplastic processes of xeroderma pigmentosum we have found two principal forms of new-growth: First, the keratosic plaque or tumor; second, the large, and at first vascular, tumor. While the tendency to malignancy is often found in the first, it is very constant in the second form; yet, on the other hand, the latter tumors frequently wither and fall. A study of the 40 reported cases of this disease shows that malignant new-growths were present in 17, and non-malignant growths (at the time of report) in 6 cases. Further, that in 9 cases in which no new-growths were noted, in 5 the children were respectively two and a half, three and a half, five and a half, six, and twelve years, ages far too young to warrant the prognosis of the future exemption from new-growths. Of the remaining 4 cases, 2 were seventeen, 1 eighteen, and 1 twenty-two years of age. Their chances of immunity were better, yet the ugly fact obtrudes itself that in one case new-growths, which underwent malignant degeneration, appeared at about the thirty-fifth year. This, however, was in the rather exceptional case of Heitzmann.

Of the 17 cases in which malignant new-growths appeared, epithelioma was noted fourteen times, melano-sarcoma once, sarco-carcinoma once, and cancer in one case. Out of my own 7 cases, epithelioma occurred in 3 children.

The 6 instances of benign new-growths are as follows: Papillary warts, 2 cases; papilloma, 2 cases; granuloma and pannus, of each 1 case. This foots up new-growths of both kinds in 23 out of 40 cases, and experience shows that in any of the 6 cases of benign new-growth malignancy may occur. The dates, as far as can be ascertained, at which the malignant new-growths began are as follows:

From four to ten years	8 cases.
" ten to twenty years	7 "
" twenty to thirty-five years	2 "
Total	17 cases.

These statistics would seem to indicate that the period of greatest malignancy is under ten years, nearly as great until twenty years, and not great beyond the twentieth year.

Of the 40 cases of xeroderma pigmentosum 21 were males and 19 were females. Several members of a family were usually attacked, in some cases males alone, in others the females, and in still others both males and females.

The occurrence of malignant growths, particularly epithelioma, in such young subjects is remarkable and exceptional, and is to be explained on pathological grounds to be considered shortly. What has struck me as being equally singular is that there is no evidence, either during life or after death, in any case, of metastasis. This seems to be another peculiarity of this wonderful disease. It is impossible to give an exact description of all of these tumors. In general they are red or purple, sessile or pedunculated, fungating or raw; smooth, sometimes incrusted, again oozing, and often the seat of hemorrhage.

The pathology of this disease has been well studied by Kaposi, Geber, Neisser, and Pick, and it is to their writings that I am indebted for the facts I present.

Neisser gives the histological appearances of the skin of xeroderma pigmentosum as follows: The pigment is distributed in isolated spots, similar to melanotic tumors, and is seated in the deep layers of the epidermis, and rarely in the corium. The pigment is precisely similar to that of melanotic new-growths, and differs from that of ecchymosis. In spots where there is an accumulation of pigment, the interpapillary prolongations of the rete Malpighii are more abundant and compressed than in the normal state. This augmentation in number and size of these prolongations seems to be the first stage of the ulterior epithelioma. It was from this fact that Kaposi was able to predict the development of epithelioma in one of his cases.

The little dirty-yellow, warty elevations undergo corneous transformation, and there is in them a rapid increase of the papillary vessels. The atrophic condition is similar to that of senile atrophy of the skin, and involves the connective tissue of the papillæ and upper portion of the derma. The subcutaneous tissues are usually not altered, at least not until late. It thus happens that the morbid skin usually freely glides over it.

In the white spots there is an entire absence of pigment, and the line of demarcation between the thinned epidermal and capillary layers is perfectly regular. With atrophy of the epidermis there is absence of pigment, while in spots where it is thickened the pigmentation is great. The production of the pigment seems to depend on the alteration in the vessels.

Leloir's results are similar to the foregoing. He found in the atrophic spots very few vessels, and an absence of the papillary loops of capillaries. In the superficial layers of the derma embryonic cells were abundant, and also there was a large quantity of elastic fibres in the deep layers of the papillæ, which seemed to have replaced the atrophied connective tissue. This condition probably gives rise to the hide-bound tension observed in some cases.

Pick says that at first the epidermis is entirely unchanged, but thickened, and from it conical processes pass into the rate, which reduce and thin it. In the corium there is an abundance of vessels, the endothelium of the same and of the capillaries is swollen and folded, so that it obstructs the lumen. Around the adventitia of the vessels are masses of small-cell infiltration, particularly in those of the papillæ. Pigment-deposit keeps pace with the invasion of the vessels and with the small-cell infiltration of the corium. The cell-infiltration is undoubtedly the carrier of the pigment. From this it would seem that in the majority of the pigmentations the cell-increase is not great, but beginning with the keratosic patches it becomes more and more abundant. In the fawn-colored pigmentations, in which it almost conclusively appears that the rete is the seat of pigment, the vessels are dilated and distended with blood, and it is evident that they have their origin in the red spots. While the keratosic or warty patches are also related to the pigmentations, there is found much variation in the amount of cell-infiltration and vascular change. This fact explains why some tumors are very vascular and others firm and dry.

With these facts before us, Kaposi's explanation of the occurrence of epithelioma at such early ages as being due to the rapid changes going on in the epithelial layer in the production and rapid disappearance of new papillæ and epithelium, and of the pigment-carrying elements, is very satisfactory.

The occurrence of melanotic sarcoma and of carcinoma in these growths demands more extended study in the future.

Funk[1] thinks that the disease is caused by a micro-organism which he says that he found in the sero-purulent fluid from the conjunctiva, and in a red nodule from the right eyelid of the case seen by him. Funk's case[1] is reported so briefly that it is of no use for statistical purposes. It was the case of a boy who was attacked at the end of the first year after birth. A sister had died as a result of xeroderma pigmentosum at the age of seven.

Treatment.—Though every suitable external remedy has been tried, no case of xeroderma has ever been cured. Our measures, then, should be directed toward placing the skin at rest, and removing any possible source of irritation to the morbid parts. Especial care should be taken of the eyes, nose, mouth, and ears, since in these situations the disease expends its activity and malignancy. Details of this preventive treatment will suggest themselves as the cases present. Knowing, so well as we do, that these pigmented warts carry in their train such terrible consequences, they should be removed as soon as possible with the sharp spoon. In fact, all small and large tumors should be removed as soon as possible. There need be no fear of excessive hemorrhage, and if taken early one is warranted in expecting prompt cicatrization. Especially should this procedure be followed in small and commencing lesions about the eyes, nose, mouth, and ears. The sooner they are destroyed, the greater is the immunity of the patient to further growth, and, perhaps, malignant degeneration. All large tumors should be removed, and the subjacent tissues scraped thoroughly, if necessary, to the periosteum and bone.

In the following table the essential facts of all the recorded cases are given :

No.	Age.	Sex.	Age at onset.	Age when tumors appeared.	Nature of tumors.	Observer.	Remarks.
1	3½ years.	Female	7 months	None		R. W. Taylor	In this case there were telangiectases, pigmentations, and atrophy, but no new-growths.
2	13 years.	Female: second child, and the first one afflicted. Sister to Cases 3 and 4.	14 months	3 or 4 years	Angio-myxoma; later, epithelioma.	R. W. Taylor	The disease in this child was more severe than in her sisters. The warty tumors, in 1876, were angio myxoma; from that time on, until 1883, they grew and developed into true epithelioma.
3	7 years.	Female; fifth child, and third and last afflicted.	Less than a year.	About 14 years.	Extensive pannus-growths of the cornea and opacity.	R. W. Taylor	Telangiectases, pigmentations, atrophy, and tumors like keratosis senilis in well-marked form until fourteen years of age, when the eye was attacked. Inveterate pharyngo-nasal catarrh and chronic otitis media began about the same time.
4	8 years.	Female: sixth child, and second attacked. Seven other children healthy.	Less than a year.	3 or 4 years.	Granuloma	R. W. Taylor	Telangiectases and pigmentations very marked; atrophy slight. Appearance of keratosic tumors at fourth year. Remained indolent several years. From 1878 to 1883 one near the temple developed into a granuloma of the size of a hazel-nut.
5	7½ years.	Male: second child. Cousin to Cases 2, 3, and 4.	1 year	7 years	Epithelioma	R. W. Taylor	Telangiectases, pigmentations, and keratosic tumors of face. Abscess of the parotid, from mumps, was followed by epitheliomatous infiltration of the parts, erosion of the deep arteries, and death.
6	12 years.	Female: sixth child—first, third, fourth, and fifth healthy. Sister to Case 5.	6 months	None		R. W. Taylor	Telangiectases, pigmentations, and slight atrophy about face. Very mild course of disease; no new-growths. Death by drowning.
7	12 years.	Female. Eldest of six children.	0 months	5 years	Epithelioma	R. W. Taylor	All of the lesions very severe. Tumors about the nose and eyes became of large size and epitheliomatous. Death from marasmus at thirteen years; became malignant at twelve years.
8	18 years.	Female	Early childhood.		No history of tumors.	Hebra and Kaposi.	Case showed telangiectases, pigmentations, and much atrophy. Ulceration of cornea; ectropion severe. Nose and ears disfigured by contraction from atrophy. Death, when twenty-five years of age, from cancer of peritoneum.
9	10 years.	Female	Early childhood.	11 years	Epithelioma	Hebra and Kaposi.	Telangiectases and pigmentations; much atrophy and deformity of the face. A large, pear-shaped tumor developed on the side of the nose. Died of cancerous cachexia when thirteen years old.
10	8 years.	Female	Nearly 2 years.	4 years	Sarco-carcinoma.	Geber and Kaposi.	Telangiectases, pigmentations, atrophy, catarrhal ophthalmia, and photophobia. Malignant tumors removed from the region of the nose when seven years old; wound healed by granulation; return of new-growths.
11	6 years.	Female. Sister to Case 10, who was next oldest child; two younger ones were spared.	1 year	None		Geber and Kaposi.	The lesions in this case were telangiectases, pigmentations, and atrophy. Further history not given. Kaposi regarded the onset in this case as precocious.
12	5½ years.	Female; first child	In the second year.			Kaposi	A deaf mute. Meningitis when six months old. Telangiectases, pigmentations, and contraction of nasal and oral orifices from atrophy.
13	2½ years.	Male. Brother to Case 12. Parents young and healthy.	In the second year.			Kaposi	Not seen by Kaposi, who says that the parents' description convinced him that the affection was xeroderma pigmentosum.
14	17 years.	Male	There is no evidence whatever of the early or late development of the affection in this case.	12 years	Epithelioma	Kaposi	The history of this case is very unsatisfactory. At seventeen years of age there were pigmentations and ulcerations on the face, said to have existed five years, at first regarded as cancerous by Kaposi, then as syphilitic, and cured by appropriate treatment. In a year and a half numerous cancerous nodules on the face, eyelids, cheeks, nose, and chin appeared, together with pigmentations and telangiectases. If this *is* a case of xeroderma pigmentosum, it is one of late and obscure evolution. The relation of the syphilitic diathesis is not dwelt upon. No history of disease on the arms, legs, or other parts usually involved.

---

[1] Bakteryjew Xeroderma Pigmentosum.

[1] Przypadek xerodermatis pigmentosi, Gazeta Lekarska, 44 and 52, Warsaw, 1885. Quoted in Virchow and Hirsch's Jahresbericht, Band 2, 1886, p. 497.

No.	Age.	Sex.	Age at onset.	Age when tumors appeared.	Nature of tumors.	Observer.	Remarks.
15	22 years..	Male..........	16 years.....	20 years........	Epithelioma	Kaposi..........	First lesion appeared upon cheeks and nose. When seen by Kaposi there were ephelides, cicatricial spots, and telangiectases. Anterior to the right ear, under the left eye, on the nose, face, and lower lip were epitheliomatous nodules. Disease limited to the face and neck. This would seem to be a case in which the evolution of the disease began at the sixteenth year. It is to be regretted that the early symptoms and course are not given. There is an absence in the history of the classical evolution of the disease, of telangiectases, pigmentations, atrophy, keratosic tumors, and, later, malignant degenerations. These two cases of Kaposi, of very late onset, with the exception of those of Vidal and Heitzmann, at nine years, are the only recorded instances in which the disease did not begin in early infancy.
16	9 years..	Female...............	2 years.. ...	4 years.........	Warts and epithelioma.	Kaposi..........	History very fragmentary, and wanting in many respects. Affection limited to the face. Patient the eldest of nine children, seven girls and two boys.
17	40 years.	Male.................	9 years......	Uncertain; probably over 35 years.	Epithelioma	Heitzmann	Freckle-like patches on the face and hands. One lesion resembled rodent ulcer. New nodules appeared every six months.
18	17 years..	Female. Three brothers and one sister living. Four sisters died of infantile complaints.	6 months	None....	....	Duhring..........	Pigmentations the predominating lesions; telangiectases not numerous nor well defined; atrophic spots sparse and small. A good example of mild form of the disease in the stage of quiescence. Head, neck, arms, hands, legs, and feet involved. Mother died of cancer of uterus.
19	24 years..	Male.................	3 months	22 years	Epithelioma ...	Neisser	Mother had had syphilis; father died of obstruction of œsophagus. Patient an imbecile; pigmentations, telangiectases, atrophy, and nodules of face.
20	22 years..	Male. A brother and sister of father of Cases 19 and 20 were idiots.	3 months	None.	. ...	Neisser...	Not seen by Neisser. Mother said he was exactly like his brother.
21	18 months.	Male; strong and well nourished.	Not stated ...	None..........	....	Rüder; quoted by Neisser.	Pigmentations, telangiectases, and pin head-sized warts. Child too young to judge of course of disease.
22	4 years...	Male; strong and large.	Not stated...	None.........	....	Rüder; quoted by Neisser.	On the face, back of hands, and forearms were telangiectases, pigmentations, and atrophy. Swelling of the conjunctivæ; conjunctivitis; great sensibility to light.
23	5 years...	Male; strong and chubby.	Not stated ...	None......	....	Rüder; quoted by Neisser.	The usual red and black lesions and atrophy upon the face and forearms; yellowish-gray wart on the ear, and small ones on the forearms. Conjunctivitis; marked photophobia. Scar on the lip, from which a warty growth fell spontaneously.
24	9 years ..	Male; healthy and strongly built. Two intermediate girls.	Not stated ..	....	Probably epithelioma.	Rüder; quoted by Neisser.	Red and black spots and atrophy; numerous warts over the face; conjunctivitis. A tumor the size of a hazel-nut was removed from the under lip; recurrence in eight months.
25	11 years..	Male; strong and well nourished.	Not stated....		....	Rüder; quoted by Neisser.	Red and black spots and atrophy; ectropion and conjunctivitis. A pea-size ulcerating wart on the right cheek: numerous radiating scars on same.
26	10 years..	Male. Three healthy girls and a boy were born between Cases 25 and 26.	Not stated....	....	Not known.	Rüder; quoted by Neisser.	A hearsay case. Parents said child died, when ten years of age, of a cancerous swelling of the temporal region. Cases 21 to 26 were brothers.
27	11 years..	Female; healthy. Two healthy brothers.	Toward the age of 3 years.	9 years........	Epithelioma; fungoid.	Vidal............	Pigmentations, telangiectases, atrophy, conjunctivitis, and slight ectropion. Vegetating tumors and ulcers of the face near the nose, ears, and on the chin. Removal of large tumor, and no tendency to recur.
28	11 years..	Female; healthy.	18 months	4½ years... .	Epithelioma; fungoid.	Vidal.	Not seen by Vidal. Parents' description convinced him of the nature of the case. Tumors, probably epitheliomatous, on the face. Death from exhaustion at the age of eleven.
29	12 years..	Male; healthy. Of a family of four boys and one girl.	Toward the age of 2 years.	6 years........	Epithelioma; fungoid.	Vidal............	Telangiectases, pigmentations, atrophy, fungus of cornea, and ectropion; numerous tumors of the face and neck. A tumor existed on the right wrist, which fell off; keratosic tumors of the hands.
30	10 years..	Male; healthy. Paternal uncle died of cancer of the stomach.	2 years	At 5 years, keratosic; at 7 years, fungous tumors.	Epithelioma; fungoid.	Vidal............	An unusually severe case. Usual dermal lesions. Numerous and extensive tumors of the face; some fell off. Ulceration involved several parts of the face and destroyed the nasal bones and portions of the superior maxillaries. Death from exhaustion. No evidence of metastasis.
31	5 years...	Male. Eldest brother and sister healthy.	2½ years.....	Keratosic tumors appeared at 4 years.	(?)	Vidal............	Owing to the youth of this child the disease had not progressed to malignancy. There is evidence of keratosic tumors on the nose, cheek, and upper lip. The history of the case to date does not warrant a diagnosis of epithelioma, which very probably might develop later on, as it did in his brothers, Cases 29 and 30.
32	19 years..	Female; oldest child..	....	... .	Melanotic tumors; sarcoma fuso-cellulare melanoticum (Chiari).	F. J. Pick	Case remarkable for the extensive distribution of pigmentations on the face, neck, chest, arms, forearms, hands (dorsum); legs and feet thickly covered. Tumors on the lower right eyelid and legs.
33	17 years..	Female; second child..	....	. . ..	Papillary warts..	F. J. Pick	Large pigmentations (black, brown, and red) over the face, neck, shoulders, arms, hands, legs, and feet, sparing the palms and soles, and lighter pigmentations around the navel, genitals, and anus. Keratosic tumors on the face and body; small ones on the extremities. Walnut-sized tumor of the gum of lower jaw; removal.
34	2¾ years.	Male; twelfth child...	....	.. ..	Papillary warts..	F. J. Pick	Pigmentations on the face and hands. As in all young subjects, telangiectases very numerous, and large atrophic patches. Pick's cases are particularly satisfactory in many respects, since they were under observation three years. The majority of the reported cases were observed during periods entirely too short.
35	12 years..	Female.	Between 12 and 18 mos. No history of prodromal erythema.	11 years........	Papilloma; fungoid.	H. R. Crocker....	Pigmentations, telangiectases (not numerous); atrophic spots on the face, head, neck, chest, and extremities. Large tumors on the right side of the face, ears, cheek, nose, and chin. Ulcers from breaking down of tumors. In a foot-note Crocker states that his view, that the tumors were papillomatous, and not epitheliomatous, was confirmed by Marcus Beck.
36	10 years..	Female. Sister of Case 37.	Between 12 and 18 mos.	Ulcers at about 4 years.	None...........	H. R. Crocker....	Pigmentations numerous; vascular and atrophic spots less numerous. About six ulcers on the face; no tumors. Some ectropion, conjunctivitis, and photophobia.
37	9 years...	Male; healthy. Brother of the two sisters, Cases 35 and 36.	Between 12 and 18 mos.	Ulcers at 3 years.	Papilloma; verrucoid.	H. R. Crocker....	Pigmentations of the face, neck, arms, and forearms; much atrophy of the face; very few telangiectases; no keratosic tumors. Large tumor of the left cheek removed by the boy's mother. Pterygium of both eyes.

No.	Age.	Sex.	Age at onset.	Age when tumors appeared.	Nature of tumors.	Observer.	Remarks.
38	17 years	Male; second child. First child died at twelve years; skin unaffected.	2 years	None		J. C. White	An excellent illustration of the pigmented and mild form of the disease. Pigmentations, dark and numerous, over the face, neck, forearms, and backs of the hands; much atrophy; numerous telangiectases. No tendency to malignant new-growths. Dr. White believes that there is no pathological relationship between the telangiectases and the pigmentations, but that the latter may be the initial lesions.
39	3 years	Male; well grown; sixth child. Brother of Case 38. Third, fourth, fifth, and seventh children healthy.	18 months	None		J. C. White	Also an excellent illustration of the mild pigmented form of the disease. The immunity of this young child and of his brother, aged seventeen, from malignant growths furnishes no guarantee for the future.
40	42 years	Male	In the second year.	Probably within 10 years.	Epithelioma	Dubois-Havenith.	First symptoms were said to be "sunburn" on the face, hands, and forearms, followed by diffuse red spots, which became brown. On the face and arms raspberry-sized tumors appeared. Cauterization and ablation of these were followed by their return in most instances. Pigmentations became dark in summer and pale in winter. Occasional pruritus accompanied by desquamation. Patient was the father of four children, three of whom were healthy, and one died of marasmus; none showed signs of xeroderma pigmentosum. When first seen by Havenith, patient had ulceration of the ear-lobe of ten years' standing, and there was evidence of destruction of the tissues of the ears and nose. A cancerous tumor of the lower lip appeared, was cut out, and returned. Like all cases seen about and after puberty, this one lacks much of its early history.

THE MICRO-ORGANISMS OF MALARIA.[1]

By M. B. JAMES, M.D.,

NEW YORK.

The attempts to discover the cause of malarial disease are of considerable historical interest. From earliest times the existence of a contagium vivum has been generally assumed, by reason of the peculiar clinical features of the disease itself. Up to 1879 most of the hypotheses that were offered assumed that some one of the fresh-water algæ was the exciting cause. These observations were never confirmed, and obtained but little belief.

In 1879, Klebs and Tommasi-Crudeli isolated from the soil of the Roman Campagna a bacillus which they believed to be the cause of the malarial diseases existing in that neighborhood. They obtained pure cultures of the organism, and stated that injection of these cultures into rabbits was followed by typical intermittent fever, with organic lesions similar to those found in persons dying of malarial disease. They gave to the organism the name bacillus malariæ. Their results were not confirmed by subsequent observers. It is now generally believed that the so-called bacillus malariæ has no connection with the disease. Yet, until Laveran published his paper on the so-called plasmodium malariæ, the work of Klebs and Tommasi-Crudeli was the most important attempt that had been made to discover and define the cause of intermittent fever.

The first work on the plasmodium malariæ was published in 1881 by Laveran, a French army-surgeon in Algiers. He discovered and described, in the blood of his cases, certain appearances that had never previously been noted. He offered a new interpretation of other phenomena that had long been recognized in malarial blood, but not before explained. To account for all the phenomena observed, he assumed the presence in the blood of a parasite, a polymorphic organism belonging to the animal kingdom.

Since Laveran's paper, much work has been done on this subject, though not a great deal has been accomplished beyond a confirmation of statements. In Italy, Marchiafava and Celli have devoted much time to the study of this question. In this country, Councilman and Osler have studied it most. At present, our knowledge of the organism may be briefly summed up as follows: In the blood of persons suffering from malarial disease there is a series of phenomena not yet found under any other conditions. These phenomena point to the presence of an animal parasite. The appearances that we get are one or more of the following:

First.—Colorless protoplasmic bodies inside the red blood-corpuscles. They vary in size from one-fifth to almost the whole diameter of the corpuscle. They exhibit active amœboid movements. Some contain scattered granules of brownish-black pigment; others are unpigmented. The red corpuscle which contains the amœboid body is commonly larger, flatter, and paler than normal.

Second.—We find disk-shaped bodies of colorless protoplasm. They are somewhat larger than a red blood-corpuscle. They show no amœboid movements. They contain scattered pigment-granules. They are apparently a later stage of the form first mentioned, which has come to occupy the entire corpuscle, and has then entered upon a cyst stage.

Third.—We find forms similar to the cysts, but in which the pigment-granules have become massed at the centre, while the protoplasm is undergoing segmentation. Then there are found various stages in the transition from the encysted to the segmentary form.

Fourth.—We have the small masses of protoplasm that have resulted from the segmentation of the cyst form. They are commonly somewhat oval in shape. In fresh blood it is difficult or impossible to distinguish them from blood-plaques. In dried blood they show a tolerably characteristic bipolar staining with aniline dyes.

Fifth.—We have hyaline bodies of crescentic shape, in length rather more than the diameter of a red blood-cell. They have, in every case, a collection of pigment-granules in their centre. These are the so-called "crescentic bodies."

In some cases there are found bodies resembling the crescents closely in character, but elliptical or round. The crescents may have a delicate curved outline opposite the concavity or convexity, or both, but this outline never reaches quite to the tips of the crescent.

Lastly, there are the various motile bodies. These are: First, flagellated bodies. A round or pear-shaped body, about one-half the diameter of a red blood-cell. It contains pigment-granules, and is provided with from one to four flagella, which show an active lashing motion, and by means of which the organism moves about in the blood-plasma. The flagella are several times as long as the diameter of a red cell. Their motion is active enough to set up well-marked movements on the part of the neighboring blood-corpuscles.

Secondly, free flagella have been described. They seem to have become detached from their bodies, and to be capable of leading an independent existence. They exhibit active movements.

Thirdly, some observers have described hyaline pigmented bodies with an actively moving, undulating periphery.

---

[1] Read at a meeting of the New York Pathological Society, held January 25, 1888.

Pigmented white blood-corpuscles have been described. I have not seen them; nor have I in my cases met with free flagella or the bodies with undulating periphery. All of the other forms I have had frequent opportunity to study.

Next, as regards the interpretation of the appearances described in the blood: It is believed that the unpigmented amœboid body makes its way into a red blood-corpuscle, and lives and increases in size at the expense of the latter. It becomes pigmented, the pigment-granules being changed to hæmoglobin. It has been demonstrated that the granules contain iron.

Having come to occupy the entire, or almost the entire, corpuscle, it enters upon a cyst stage, during which the pigment-granules make their way to the centre, and segmentation of the periphery takes place, thus forming spores, which are subsequently set free. Each spore then begins again the same life-circle.

The biological relation of the crescentic and flagellated forms to the others has not been made out. But there are, among the lower animal organisms, many polymorphic varieties, which at different periods of development exist as spores, amœboid bodies, cysts, and flagellated organisms. Among the protozoa, some forms (sporozoa, Leuckart) develop falciform spores which in appearance resemble the crescents.

As regards the relation of the various forms of the organism to the types and periods of the disease: The description that I have given applies to tertian intermittent. With quartan I have had no experience; but Golgi states that in this form, which is the prevailing type in Pavia during the autumn months, the organism exhibits certain peculiarities. In general, the various forms are more clearly marked off from one another. The segmentation forms are especially clear. He also states that in every case the complete development of the organism corresponds to the interval between two paroxysms of the disease.

The paroxysm seems to be the period at which the segmentation and setting free of spores takes place. This is now tolerably definitely settled. The discovery in the blood of the segmenting bodies justifies the positive prediction that the patient will have a chill at some time within two hours. According to Golgi, immediately after the paroxysm one finds free spores and unpigmented amœboid bodies. During the day of intermission the pigmented amœboid forms gradually increase in size till six or eight hours before the chill, when the cyst stage is met with. Immediately before and during the chill one finds the segmenting forms.

In my own cases I have found the segmenting forms always just before and during the paroxysm, and at no other time. I have, however, found the pigmented amœboid bodies at all times, and most numerous during the paroxysm.

It is said that in some epidemics the organisms remain unpigmented throughout the disease.

The crescents and the bodies allied to them occur in chronic cases, usually in those associated with malarial cachexia. This point is one upon which all observers agree.

In two of my cases there were at the same time crescents and amœboid forms. Both of these forms commonly occur in greater number in severe than in light cases, though to this there seem to be exceptions. The various flagellated forms may occur in any case; but in only a small number of cases in blood from the finger. I found them in only three of my cases.

During the past autumn I had an opportunity to study the blood of thirty-five cases which were undoubtedly malarial disease. In thirty-four of the cases I found the hæmatozoon. In one case the examination was negative, but here I was able to examine the blood only on one occasion. Often, when the number of the organisms in the blood is small, one may look through several slides before finding them.

In my cases, as in those published by others, the amœboid forms, pigmented and unpigmented, occurred in the acute stages of the disease; the crescentic forms, in the chronic stages. In no case have I failed to find the organism, where the patient presented a clear clinical picture of malarial disease, and where I was able to make a number of examinations of the blood.

The examination for the organism has considerable diagnostic value. In several cases I have been able to diagnose or to exclude malarial disease by examining the blood, where the symptoms alone were not characteristic enough to make a positive conclusion possible, and where the subsequent history has borne out the results of the microscopic examination.

The microscopic technique is simple. The blood is best examined fresh, spread out in the thinnest possible layer—the rouleaux of corpuscles broken up. High-power objectives are necessary. A $\frac{1}{12}$-inch oil immersion answers well.

Stained specimens are best prepared by drying the blood in a very thin layer on a cover-glass, which is then passed through a flame, as in examining for bacteria. It may be stained in a watery solution of an aniline dye, washed out in water, or partly decolorized in alcohol, and mounted, as usual, in balsam. Fuchsin and methylene blue give the best results. I find methylene blue most satisfactory, the red corpuscles staining light green, and the hæmatozoa blue.

Unpigmented amœboid bodies are best studied in stained specimens. The pigmented amœboid bodies, which are those most commonly met with, are best seen in fresh blood. The crescents also show most satisfactorily unstained. The segmenting bodies and free spores are best studied after drying and staining.

The apparent effect of medication on the organism is important.
